KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*,
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

BIOGENIC STIMULATORS

Third Witch:

Scale of dragon, tooth of wolf
Witch's mummy, maw and gulf
Of the favin'd salt-sea shark,
Root of hemlock digg'd i' the dark,
Liver of blaspheming Jew,
Gall of goat, and slips of yew
Sliver'd in the moon's eclipse,
Nose of Turk, and Tartar's lips,
Finger* of birth-strangled babe,
Ditch-delivered by a drab,
Make the gruel thick and slab:

* Why not placenta?

Add thereto a tiger's chaudron
For the ingredients of our cauldron.

All:

Double, double, toil and trouble;
Fire burn, and cauldron bubble.

Second Witch:

Cool it with a baboon's blood,
Then the charm is firm and good.

Macbeth, Act IV, Scene I.

The late Sanford Gifford said (*Hand-book of Ocular Therapeutics*): "The difficulty in estimating the value of

therapeutic agents administered in an attempt to aid this mechanism (the defensive mechanism of the body) is, therefore, obvious. This explains the remarkable variance in reports of different observers and often of observers whose clinical judgment is usually very reliable, as to the effect of various therapeutic agents. A chance series of cases with a fortunate outcome may convert an ophthalmologist of unquestioned standing into an enthusiastic advocate of a measure which has little to recommend it theoretically, and which in the hands of other men may later prove absolutely worthless. Thus it is necessary to greet the first reports on the use of any new agent with a certain amount of reserve. Agents of recognized value should not be abandoned in favor of new ones unless the evidence in favor of a change is convincing. The evidence of a small number of case reports alone is apt to be unsatisfactory, and one will be slow to take up the use of a new method unless there exists a certain foundation of theoretical and experimental reasons why the new method is likely to prove of advantage."

The fundamental common sense in this thought of a great ophthalmologist bears repetition today, when one is bombarded by press releases of new and often astounding discoveries of cures in the medical sciences. The evils of premature, spectacular publicity are too well known to be discussed here, nor is it necessary to detail the harm done to the public, and eventually to the entire medical profession, by such propaganda, either willful or innocent. The history of medicine is filled with these false alarms that have misfired, or, what is less serious, backfired into the faces of those responsible. What we never discover is the total cost to the afflicted, either in mental distress engendered by their false hopes, or to their pocketbooks, which in our material-

istic age seems to be more important. What is morally worse, by far, is the example set to our younger men who see the leaders "getting away with it" and thus are inspired to imitation.

Elsewhere in this issue will be found an article by Dr. Dan M. Gordon on the "Treatment of Retinitis Pigmentosa with Special Reference to the Filatov Method." It will bear careful study, for it details the history of the flotsam and jetsam of the wrecks of ideas regarding the treatment of this disease. This paper reemphasizes what Duke-Elder has so ably expressed. "None of them (remedies for pigmentary degeneration of the retina), however, has shown anything approaching lasting or consistent results, and it is probable that the temporary improvement following many of them is due to an increase in the metabolic activity in the eye rather than to any specific action. In the assessment of all of them it is well to take into consideration the natural fluctuation in the progress of the disease, as well as the enthusiasm of the practitioner and the credulity or the desperate hopefulness of the patient."

One has no quarrel with Filatov and his co-workers over the attempt to treat this so far hopeless ocular condition by any means whatsoever, fantastic as those means may seem to us. The mysterious and at present unknown action of his "biogenic stimulators" requires investigations of the most rigid and controlled sort, before they can be hailed as the long sought philosopher's panacean stone of ocular therapeutics. The work of Gordon and others is an attempt to evaluate and clarify the premise of Filatov. It is necessary that such work be done, under most careful scientific scrutiny and in the Eye Institutes that are especially equipped to carry out such meticulous study.

It would seem, from a study of the available Russian literature, more or less

abstracted to be sure, that the tissue therapy of Filatov is a new way of introducing a foreign-protein reaction, although differing in some respects, perhaps, from such biogenic stimulators as milk, typhoid vaccine, and Coley's serum. A severe febrile reaction has been produced in a "moon-blind" horse by the injection of sterilized horse feces with some improvement of his periodic ophthalmia (author). Sterile abscesses have been created as biogenic stimulators by many means (seton, croton oil, cupping, sterile blood, and so forth) and "laudable pus" was celebrated a long time ago. In fact, the witches' brew of Shakespeare may well contain the pharmaceuticals we are looking for, if Filatov's work with offal is substantiated.

No, the quarrel is not with Filatov and his group, primitive and slightly obscene as his treatment may seem to be to us. It is with the noisy group of fellow travelers in this country who by aggressive publicity measures seek to promote this treatment in the press for political purposes. This is the true danger to science.

On April 28, 1946, the *New York Herald-Tribune* carried a descriptive announcement hailing in enthusiastic terms the Filatov method. The ophthalmologists of this country were besieged with requests by their patients, afflicted with retinitis pigmentosa, for this treatment. In a personal communication, Dr. Robert Leslie, business manager of the *American Review of Soviet Medicine*, stated that the American Society for Russian Relief issued this newspaper release to the press, which he had not authorized. However, in the June, 1946, issue of the *American Review of Soviet Medicine*, four out of the nine main articles were by Filatov, or Filatov and Verbitska, considering the treatment of retinitis pigmentosa and the fantastic results of their methods of treatment (85 successful re-

sults out of 110 cases). Dr. Leslie circularized the ophthalmologists of this country with letters calling attention to the articles and offering a copy of the issue for one dollar. The magazine *Newsweek* has carried several articles about this treatment, and not long ago a group was formed in New York, financed for the sole purpose of promoting and perhaps exploiting the Filatov treatment.

It is to the credit of American medicine that there has been no blind stampede into this grotesque field of therapeutics. Scientific work will rise or fall upon its own worth and integrity. Scientific truth will ultimately prevail and all the subversive trumpets in Christendom or in pagan countries cannot promote for long an issue that is basically unsound. They can only succeed in confusing us and hiding for a time fundamental errors. These noisy promoters often end up by mistreating the common man whom they pretend to protect and whose welfare they affect to coddle.

The danger to science of replacing the mortarboard by the pileus, the scarlet gown of the free doctor by the black shirt of Nazism or the red one of Communism, or by the star-studded hood of the necromancer, has been sadly demonstrated only too often in the past history of man's civilization. Politics and the state have no place in the premature exploitation of any medical discovery, regardless of the outcome.

Derrick Vail.

OPHTHALMOLOGICAL STUDY COUNCIL

The third and last of the Ophthalmological Study Council courses is to be given this summer in Portland, Maine. As is usual with the end approaching, the managers are just beginning to feel some confidence in their understanding and control of the problems raised by so

large an enterprise. So far as is known, this is the only attempt by any medical specialty to meet the needs of the five-year supply of prospective specialists with less than a one-year facility for training. These courses have turned out to be far more than a stop gap. They were outstanding among the very good courses given during the period. The instructors were picked from every part of the United States. Many of them were men with international reputations. The subjects covered were such as to give the students a more comprehensive training than the purely basic courses. Finally, by weekly examinations in the subjects under immediate consideration, an earnestness of application developed rarely seen in graduate study.

Examinations serve another important end. They rate the teacher quite as definitely as the student. If a few students fail in a course, the inference is that they can't or don't take in what the rest of the class are able to absorb. That is their fault. But if a large part of the class get "busted," that is an indication that the teaching was inadequate. The teacher is to blame.

The second Study Council course, given in St. Petersburg, Florida, in November and December, 1946, and part of January, 1947, profited by the criticisms of the Boston course made by the students. The physical arrangements were more convenient. The lectures were held in the same hotel that housed both faculty and students. Clinical demonstrations in refraction were included. In the curriculum changes were minor. The greatest difference was that the lecturers had their material better in hand.

To date approximately 150 applicants have taken the course at one or the other session. This leaves some 300 inquirers who have not been accommodated. While many of these may have given up speciali-

zation, other applications keep coming in. In one final attempt to accommodate all who need this instruction, the committee has made arrangements for a third and last session. It will be held during the coming summer, a time likely to be more convenient for both students and lecturers. It will be given in Portland, Maine, a resort center with an agreeable summer climate. The facilities of the Westbrook Junior College have been made available, affording housing, feeding, and classroom accommodations at far less cost than that of the previous sessions. Because of the general approval given the St. Petersburg course, no other important changes will be made. Faculty and curriculum will be essentially the same. The aim will be to prepare the students for preceptorships. If they have the good fortune to secure residencies, they will be better equipped to make use of these opportunities. Even inferior residencies will, therefore, become more useful.

With the completion of this session, ophthalmologists will have the satisfaction of knowing that their specialty alone has at least furnished an opportunity to many men who served their country at a large sacrifice and would not otherwise have ever had an opportunity to undertake proper training. At best it will have provided a creditable foundation for many ophthalmologists, at a time when there is a decided shortage of well-trained men.

S. Judd Beach.

THE PROCTOR RESEARCH MEDAL

The Association for Research in Ophthalmology has just announced a gift from Mrs. Francis I. Proctor of Santa Fe, New Mexico, for the endowment of a research medal in memory of her husband, to be awarded for outstanding research in the basic sciences as applied to

ophthalmology. Dr. Proctor was a Boston ophthalmologist who settled in Santa Fe after his retirement and became actively interested in experimental ophthalmology, particularly as applied to trachoma and other special disease problems of the American Indians. As Consultant on Ophthalmology to the Office of Indian Affairs, he induced Noguchi to undertake his investigations of trachoma which, although in themselves fruitless, inspired a series of researches by American and foreign workers which finally proved that the agent of trachoma is a virus belonging to the psittacosis-lymphogranuloma-venereum group of viruses. In view of Dr. Proctor's passionate interest in basic investigation and the help and stimulation he gave to it in his later years, it is particularly appropriate that this research medal be founded in his name.

The Proctor Medal will differ from the other medals in ophthalmology in being open to nonclinical workers in ophthalmology. There is an increasing number of basic-science workers attached to the large university eye clinics who will become eligible for it, as well as a smaller number who are not assigned to special eye departments but are doing their major research in basic eye anatomy, physiology, pathology, and so forth.

It is the intention of the association to award the Proctor Medal sparingly so as to insure its carrying distinction. At the same time, it will not be awarded so infrequently as to impair its value as a stimulus to basic research.

The Proctor Medal would appear to fulfill a definite need and should prove a fitting companion to the Howe Medals of the American Ophthalmological Society and the Section on Ophthalmology of the American Medical Association, and to the Knapp Medal of the Section.

Phillips Thygeson.

OBITUARY

SIR ARNOLD LAWSON

(1868-1947)

Sir Arnold Lawson, one of England's most widely known and best loved ophthalmologists, died on January 19, 1947, at the age of 79 years.

Following in the specialty of his distinguished father, George Lawson, surgeon-oculist to Queen Victoria, Arnold Lawson was educated at Taylors School in London and entered Middlesex Hospital as senior entrance scholar in 1886. He was qualified in 1891.

Sir Arnold served as clinical assistant to Sir John Tweedy at Moorfields, as ophthalmic surgeon to the Paddington Green Children's Hospital, and on the staff of Moorfields. In 1914, he became ophthalmic surgeon and lecturer on ophthalmology at Middlesex to whose staff he was appointed in 1910.

During the first world war, Sir Arnold resigned from all but the Middlesex appointment to devote himself to the blinded soldiers and sailors. It is for his work among these men at St. Dunstan's that he will be forever remembered. Hundreds of soldiers and sailors blinded either in World War I or II will miss his sympathetic understanding and kindly interest even more than they will miss the great knowledge and skill which he brought to the treatment of their blindness.

CORRESPONDENCE

ANGLE KAPPA IN STRABISMUS

For the accurate determination of the angle deviation in strabismus, when the latter is measured objectively on the perimenter, the value of the angle kappa has to be added to or subtracted from the value thus found. The angle kappa (often referred to as the angle gamma with which it is almost identical) is the angle between the visual axis and the pupillary

axis. The latter is the imaginary line through the center of the pupil, normal to the cornea. It is determined by the reflection in the center of the pupil of a small light held in front of the eye. Angle kappa is considered positive when the pupillary axis is temporal to the visual axis; it is considered negative when the pupillary axis is nasal to the visual axis.

Herewith is an easy way to remember when the angle kappa has to be added or subtracted in order to arrive at the true value of the angle of squint. The angle of deviation in convergent squint may be considered a positive angle and denoted by the plus sign. For convergence is a positive function and the angle of over-convergence may be thought of as a positive angle. Similarly, the angle of deviation in divergent squint may be considered as a negative angle and denoted by the minus sign. Divergence may well be thought of as a negative function; in fact, it is often referred to as negative convergence. Thus the angle of divergence from the point of fixation on the perimeter may be considered a negative angle.

If the angles are thought of in this way, all that is necessary is simply to add al-

gebraically the values of the angle kappa and the angle of squint. Thus if the squint angle in convergent squint measures 15 degrees, and the angle kappa is plus 4 degrees, the true angle of squint is plus 15 and plus 4 equals 19 degrees. If the angle kappa in this instance is minus 4 degrees, then plus 15 and minus 4 gives us 11 degrees as the true angle of squint.

Or, if the angle of squint in divergent strabismus measures 20 degrees, we then have an angle of minus 20 degrees. If the angle kappa is plus 5 degrees, we get minus 20 degrees and plus 5 degrees, which gives us minus 15 degrees as the true angle of the divergent squint. If the angle kappa in this instance is, say, minus 5 degrees, then adding minus 20 and minus 5 gives us minus 25 degrees as the true angle of the divergent squint.

This method of considering the deviation angle in convergent squint as positive and the deviation angle in divergent squint as negative and then merely adding the value of the angle kappa is generally easier than other methods designed as memory aids.

BOOK REVIEW

LES YEUX ET LA VISION DES VERTÉBRÉS. By A. Rochon-Duvigues and. 792 pages. Paris, Masson et Cie., 1943.

This volume presents an exposition of the comparative anatomy and comparative physiology of the eye that is considerably more extensive than would be possible in a zoological handbook. The morphology of the human eye occupies the first 150 pages. The chapter on the origin of the vertebrate eye outlines the contributions of paleontology, comparative anatomy, and comparative embryology. The

remainder of the book is a systematic exposition of the anatomy, histology, and the functions of the eye in each group of vertebrates. A chapter is devoted to the eyes of the cyclostomes, the several orders of fishes, the amphibians, the four orders of reptiles, the birds, and the mammals. Five hundred beautifully clear, half-tone illustrations, chiefly from histologic preparations, clarify the text instead of merely decorating it. They also decorate it. There is an adequate bibliography in each section.

F. H. Haessler.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

PHYSIOLOGIC OPTICS, REFRACTION AND COLOR VISION

v. Bahr, Gunnar. The effect of peripheral rays in testing the light sense. A study on the importance of the pupillary area. *Acta. Ophth.*, 1941, v. 19, pt. 2, pp. 114-123.

This study was done on eight medical students, using the Gullstrand photöptometer. The patient's head was held in position by biting into a cast of his teeth that was attached to an arm on the Zeiss chin rest. The arrangement permitted illuminating the desired areas of the pupil with a 2-mm. pencil of light. The examinations showed that beams entering the pupil from the nasal field through the peripheral portion of the pupil have less stimulating effect than those which pass through central portions, and that the effectivity can decline by about 30 percent. With a dilated pupil the effective amount of light is therefore not in direct proportion to the size of the pupil, except in its central portion. The

data show that in light sense tests, which aim at discovering the function of the retina only the central pupillary area can be depended upon, and the pupil should be kept contracted with pilocarpine. (2 illustrations.)

Ray K. Daily.

DeVoe, A. G., and Dietz, V. H. Plastic visual test plates. *Amer. Jour. Ophth.*, 1947, v. 30, March, pp. 325-326. (1 figure, references.)

Heinonen, Oscar. Testing of color vision. *Acta Ophth.*, 1941, v. 19, pt. 2, pp. 109-113.

A candidate for railroad service was certified for normal color perception by one ophthalmologist, and was found color defective by another. The color perception of the mother was found defective. Inasmuch as all sons of a mother with defective color perception are color blind, the disagreement between the two ophthalmologists was decided by the findings on the mother.

Ray K. Daily.

Litinsky, G. A. **Fluctuating visual acuity.** *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 36-38.

In a 22-year-old man with unilateral traumatic cataract the vision in his good left eye was normal, when his face was turned to the left, and was reduced to 0.1 with the head in the normal position. Litinsky found that the patient had an old paresis of the left external rectus muscle, and the effort of the paretic externus to hold the eye straight produced a nystagmus, which reduced the visual acuity. When the patient's face was turned to the left, the nystagmus disappeared.

The second patient had a divergent strabismus; he could hold his eyes straight with great effort. Monocular visual acuity in each eye was normal. Binocular acuity was 0.1. This reduction is explained by an artificial myopia produced by the excessive accommodation that was associated with the exercise of strong convergence.

Ray K. Daily.

O'Brien, J. M., and Bannon, R. E. **Accommodative astigmatism.** *Amer. Jour. Ophth.*, 1947, v. 30, March, pp. 289-296. (2 figures, 4 tables, references.)

Pascal, J. I. **Cardinal points in aphakia.** *Arch. of Ophth.*, 1947, v. 37, Jan., pp. 83-84.

The author presents a diagram to aid in remembering the cardinal points of the eye in aphakia. R. W. Danielson.

Pascal, J. I. **Pressure effects in contact lenses.** *Amer. Jour. Ophth.*, 1937, v. 30, March, pp. 324-325.

Plicque, J. **Analysis of binocular vision. Part II, binocular synthesis.** *Ann. d'Ocul.*, 1946, v. 179, May, pp. 255-279.

The first part of this essay was re-

cently abstracted in this journal. Stereoscopic vision is an instantaneous phenomenon in which the sensorial factor dominates the muscular and in which the semiperipheral part of the retina is as important as the central part. In instantaneous perception the association centers add details to form a more or less complete mental picture which is of importance in the establishment of reading habits. Retinal correspondence is proved clinically and diplopia is practically impossible if it exists. In stereoscopic pictures two similar false images are presented before the eyes and create a false estimation of depth and direction because of an abnormal relationship between accommodation and convergence. Images on greatly disparate retinal areas normally are visualized separately but images on only slightly disparate retinal areas are, under certain conditions, superimposed and produce the impression of depth perception. The process of exteriorization is essentially centripetal and especially in binocular vision estimations of distance and direction are based on innate judgment as well as past experience. Binocular retinal impressions are localized at the reconstruction point of the principal and secondary axes. In a general way the horopter is the exteriorization of the visual impressions. Binocular alternation is an important factor in stereoscopic vision. Each optic radiation conveys only the impressions from the homolateral retina and therefore binocular alternation is considered essential for stereoscopic vision.

Chas. A. Bahn.

Wilson, W. H. **The Middle East adaptometer.** *Brit. Jour. Ophth.*, 1946, v. 30, Nov., pp. 645-657.

The author describes his apparatus

for determining night blindness as assembled by his British Army unit in the Middle East. No such machine was available and materials of any acceptable sort were scarce. The construction of the instrument is described in detail. It served the R.A.F. quite adequately as a form perception test, rather than merely a light perception test. (4 figures.)

Morris Kaplan.

4

OCULAR MOVEMENTS

Cristini, Giuseppe. **Clinical considerations on a case of progressive nuclear ophthalmoplegia.** Riv. Oto-Neuro-Oft., 1946, v. 21, March-April, pp. 98-107.

A woman, 30 years of age, with symptoms of pulmonary tuberculosis became afflicted at the age of 18 years with ptosis and paresis of the exterior muscles of the right eye after a long period of headaches and muscular and articular rheumatism. About 11 years later a ptosis of left upper lid and paresis of left internal rectus muscle appeared. The patient's eye condition could be diagnosed as chronic progressive nuclear ophthalmoplegia. That is a mesencephalic form of nuclear amyotrophy. (Bibliography.)

Melchior Lombardo.

Dickmann, G. H. **Total extracapsular removal of tumors of the hypophyseal-chiasmatic region.** Arch. de Oft. de Buenos Aires, 1946, v. 21, Jan.-March, p. 37.

The author uses the intradural approach, following Dandy's technique, for the removal of hypophysial tumors and favors the complete extirpation, rather than the curettage, of both the intra- and extrasellar portions of the growth. X-ray therapy must not be used as a sole treatment, but as a com-

plement to surgery. Two cases operated on successfully, one of cystic adenoma and the other of gliopithelioma, are reported to illustrate the author's procedure. (Photographs, photomicrographs and visual field charts.)

Plinio Montalván.

Filippi-Gabardi, E. **A note on the significance of the cortical center for voluntary ocular motility.** Riv. Oto-Neuro-Oft., 1946, v. 21, March-April, pp. 132-135.

In a discussion of experimental and histopathologic data the writer endeavors to demonstrate that the fronto-cortical oculogiric center controls solely the horizontal or vertical ocular movements. It is not a specific center for voluntary ocular motility.

Melchior Lombardo.

Gailey, W. W., and Morgan, G. E. **Surgical principals in strabismus.** Illinois Med. J., 1946, v. 90, Nov., pp. 274-279.

The essential questions arising in surgical care of strabismus are what muscle or muscles should be operated upon, how much is to be done, and what technique should be employed.

The choice of operation should be that procedure best known to the operator. The tenotomy is a useful operation when indicated and has been very successful when properly done. It is devoid of much of the trauma incidental to a recession. One of the indications for its application is in secondary contraction of a muscle.

Scleral trauma is to be avoided. The action of an operated muscle may be greatly affected by adhesions to the sclera central to its insertion. In re-operated eyes the authors have found the muscle firmly adherent as far back as the equator. Obviously, the muscle

action was correspondingly limited. Recession of the caruncle, an unfortunate and practically irreparable sequela can be avoided if there is less dissection of the conjunctiva and Tenon's capsule over the internal rectus.

How much to resect or recess is debatable and greatly depends on whether the anomaly is innervational, structural, or insertional. The authors' results in prism diopters of correction per millimeter of change in the position varied. The general principles laid down by them were: the maximum recession of a medial rectus should not exceed 4 to 4.5 mm., the lateral rectus 5.5 to 6 mm.; resection of lateral rectus 10 mm., medial rectus 5 mm.

Accuracy in diagnosis is strongly stressed. Especially important is the need for determining the status of the vertical muscles in all deviations. In combined deviations, correction of the horizontal deviation, if performed first, should be incomplete. The types of procedures recommended in the various deviations is discussed.

To facilitate orientation a dye dot is made at the 3, 9, 12, and 6 o'clock positions. Ten day chromic and plain catgut on atraumatic needles were found superior to silk sutures.

Francis M. Crage.

Schneck, J. M. *Voluntary nystagmus; case report.* Military Surg., 1946, v. 99, Sept., pp. 211-212.

The nystagmus in this young man was spontaneous, volitional, and bilateral. It was in the horizontal plane, pendular, very rapid, of large amplitude, and sustained. The movements of the eyes were symmetric. The oscillations were so rapid, once they were started by the individual, that they seemed to proceed in automatic fashion, in fact the factor of volition seemed

present only at the beginning and end of the activity. Francis M. Crage.

5

CONJUNCTIVA

Alvarado, P. J. *Contribution to the study of vernal conjunctivitis.* Bol. del Hosp. Oft. de Nra. Sra. de la Luz, 1946, May-June, pp. 153-168.

Incidentally the author refers to the old treatment of such cases, which consisted of covering the eye with a watch glass and strips of adhesive plaster. He discusses various theories as to causation, and various lines of treatment. He is disposed to regard the condition as chiefly arising from the combined effect of actinic light and hypovitaminosis. Particularly, he records three cases in children of the same family, in whom benefit appeared to be derived from prescribing a diet which supplied vitamins previously absent.

W. H. Crisp.

Araya C., Adrian. *Clinical study of hypovitaminosis A in the nursing mother. Test of conjunctival keratinization.* Arch. Chilenos de Oft., 1946, v. 2, Jan.-Feb., pp. 11-22.

The part played by vitamin A in various bodily functions is reviewed and the effects of its lack are discussed. The material utilized for the present research was obtained from 70 children, by the following technique. By separating the eyelids, the eyeball was exposed to the air for five minutes, at the end of which time the conjunctiva was gently scraped with the edge of a sterilized knife. The scraping was preceded by instillation of a five-percent-cocaine solution. The scraping was spread on a glass slide, stained with aniline oil and gentian violet followed by Lugol's solution, and fixed with absolute alcohol

and acid alcohol. The keratinized cells show intense staining and absence of nuclei. (References.) W. H. Crisp.

Chibber, P. R. **Penicillin in follicular conjunctivitis.** *Indian Jour. Opth.*, 1946, v. 7, Jan., p. 11.

The author describes a case of follicular conjunctivitis of six months' duration that responded to sulphanilamide penicillin ointment in one week.

Irwin E. Gaynor.

Campbell, M. D. **Conjunctivitis-acute, hemolytic, staphylococcus aureus.** *J. Michigan St., Med. Soc.*, 1946, v. 45, Dec., pp. 1615-1618.

Cultures were taken in 107 patients with this troublesome infection at the Army Air Base in Orlando, Fla.

The organisms present were non-hemolytic and slightly hemolytic staphylococcus albus and nonhemolytic and hemolytic staphylococcus aureus. The coagulose test as suggested by Thygeson was used in differentiating hemolytic staphylococcus aureus from other organisms.

Symptoms and treatment are discussed. In one case of hemolytic staphylococcus aureus infection, complicated by panophthalmitis, evisceration became necessary.

In all cases of hemolytic aureus infection the coagulose test was positive.

Francis M. Crage.

Lauda, E. **Findings and treatment in Reiter's syndrome.** *Wien. Klin. Wchnschr.*, 1946, v. 58, Feb., pp. 55-56.

Reiter's syndrome is characterized by conjunctivitis, polyarthritis, and urethritis. It usually appears within two to four weeks after an attack of gastroenterocolitis, especially dysentery, and is regarded as an allergic or anaphylactic rheumatic affliction following these

intestinal diseases. The author observed a patient who had these symptoms for three months and finally developed meningitis and encephalitis and died. The pathological report on the brain emphasized general hyperemia and perivascular lymphocytic and leucocytic infiltration. There seems no doubt that the intracranial disease has the same allergic or anaphylactic origin as the other manifestations and constitutes a part of the syndrome or a complication of it. Lauda recommends large amounts of salicylates (4 to 8 gm.) in one shock treatment and mentions that, in spite of failures, treatment with salicylates gives the best chance for success.

Max Hirschfelder.

Siotto, Giovanni. **Diffuse bilateral plasmoma of the conjunctiva.** *Rassegna Ital. d'Ottal.*, 1941, v. 10, July-Aug., pp. 400-416.

Pascheff in 1908 gave the name of plasmoma to hyperplasias of the conjunctiva which were rich in plasma cells. Such tumors are also found in bone marrow, lymph glands, orbit, and lacrimal sac.

In the eye they are most often found in the upper tarsus or superior fornix, and rarely in the lower lid. They are frequently associated with trachoma and develop slowly and are believed to result from prolonged inflammatory irritation. However, pathologists do not agree as to the etiology.

The author describes in detail the clinical and histologic changes in a case of plasmoma that occurred in a 31-year-old woman, who had trachoma. (3 figures).

E. M. Blake.

Siotto, G. **Ocular lesions from the venom of eels.** *Rassegna Ital. d'Ottal.*, 1941, v. 10, Nov.-Dec., pp. 594-609.

While cleaning eels some bile spurted

into the eyes of two patients described by Siotto. The symptoms produced were pain, burning sensation, and muco-purulent secretion. There was no corneal involvement. Experimentally, a keratoconjunctivitis was induced in rabbits' eyes. The meagre literature on the subject is reviewed.

Eugene M. Blake.

Sentoro, N. **Tumors of the plica semi-lunaris.** *Rassegna Ital. d'Ottal.*, 1941, v. 10, Nov.-Dec., pp. 586-593.

Two cases of new growth in the plica are reported. They were endotheliomas and proliferation developed in the vicinity of vessels, especially in one where definite vascular canals were evident. There was no necrosis, hemorrhage, or exudation, and only slight pigment formation was noted in one. (5 figures.)

Eugene M. Blake.

Zertuche, Abelardo. **Contribution to the surgery of pterygium.** *Bol. del Hosp. Oft. de Nra. Sra. de la Luz*, 1946, May-June, pp. 169-178.

With five illustrations of the various steps in the operation, the author gives a detailed description of the well-known McReynolds procedure, with a few slight modifications. W. H. Crisp.

CORNEA AND SCLERA

Blumenfeld, N. I. **Staining of the conjunctiva and cornea,** *Vestnik Oft.*, 1946, v. 25, pt. 3, p. 39.

An intense bilateral yellow stain of the conjunctiva and cornea, with reduction of visual acuity presented a baffling diagnostic problem, until it was discovered that the patient was insufflating powdered acridinine into the conjunctival sacs, as a home remedy for brucellosis. The stain remained un-

changed during a period of observation which extended for seven weeks, during which time visual acuity rose from 0.3 to normal.

Ray K. Daily.

Broendstrup, Poul. **Atypical marginal ulcers of the cornea.** *Acta Ophth.*, 1941, v. 19, pt. 2, pp. 163-172.

Three cases of chronic torpid corneal ulcer are reported. The destructive process began at the limbus and the deep ulcers gradually advanced toward the center. The loss of substance and infiltration were greater in the limbal zone. The adjacent episclera and conjunctiva were involved in the process, and the swollen, poorly vascularized, projecting conjunctiva looked like sickly granulation tissue. In two eyes healing was accompanied by a pseudo-ptyerygium-like extension of the conjunctiva into the bottom of the ulcers. The third was not healed when this report was made. Ray K. Daily.

Cornet, E. **The surgery of blindness due to anterior segment cicatrization.** *Ann. d'Ocul.*, 1946, v. 179, June, pp. 319-344.

In uncomplicated corneal opacities affecting vision a trephine total thickness keratoplasty is made with a 3 to 6 mm. trephine. Intracorneal sutures are placed into the implant before it is removed from the donor eye. After the transplant is placed in the recipient eye, its intracorneal sutures are fastened nasally and temporally by horizontally placed sutures. A wedge-shaped conjunctival flap based at the limbus above is drawn down over the implant and sutured to the limbus below. Complicating anterior and posterior synechias may be detached and opaque lenses removed before or after the keratoplasty. A limbal or U-shaped corneal flap incision may be used. The

flap is held in place by three vertical intracorneal sutures, one on each side and the third near the lower flap margin. The last is also used to hold the corneal wound open, that is away from the iris and lens, during the removal of synechias, cicatricial membranes, and cataracts. The creation of an epithelized descemetocoele for optical purposes may be of service in the absence of blood vessels, when there is minimal cicatricial tissue and intact corneal epithelium. Leaving Descemet's membrane intact, if possible, the trephined disc is removed, and a substratum is formed by Descemet's membrane. A wedge-shaped conjunctival flap may or may not be necessary. This type of operation which the author calls "keratocataphorase" may be performed in the center or periphery of the cornea or even in the sclera. Thirty-five operations on 22 patients are reviewed.

Chas. A. Bahn.

Doucet. **A case of disciform corneal blood staining.** *Ann. d'Ocul.*, 1946, v. 179, April, pp. 224-231.

After injury to the right eye by sling-shot, the usual inflammatory symptoms, hyphema and hypertension followed. Twenty days later, a diffuse golden opacity that could easily be confused with a dislocated lens, occupied the entire cornea. One month later the opacity had become disciform. A paracentesis was performed at that time. After six months the inflammatory symptoms had subsided and left complete seclusion of the pupil, iris atrophy, and cataract. (References.)

Chas. A. Bahn.

Hathi, H. J. **Interstitial keratitis.** *Indian Jour. Ophth.*, 1946, v. 7, Jan., pp. 6-9.

The author describes several inter-

esting cases of syphilitic interstitial keratitis. One patient was cured after nine years of continuous antiluetic therapy, a second cleared up after 18 months and only when his wife was treated. The last had congenital lues complicated by tuberculosis of the lungs and knees. Irwin E. Gaynon.

Hermann, C. **Lattice-like dystrophy of the cornea.** *Ophthalmologica*, 1946, v. 112, Dec., pp. 350-363.

The report concerns a Swiss family of which eleven members belonging to two generations were examined by the author. The clinical picture was typical of lattice-like (reticulate) corneal dystrophy in its different stages. The hereditary transmission was of the dominant mode. A keratoplasty performed on one member (50 years of age) furnished material for pathologic examination. The corneal epithelium was very irregular, thickened in some and reduced to one or two layers in other places. Bowman's membrane was absent. The main pathologic change was the deposition of amorphous or granular, basophilic, and acidophilic masses and concretions in the anterior layers of the stroma. The acidophilic masses were found only within the lamellae, the basophilic ones within and between the lamellae. The author gives an excellent description of the evolution of the disease.

Peter C. Kronfeld.

Just Tiscornia, Benito. **Semiological and physiopathological considerations on a case of retinal angiosclerosis.** *Arch. de Oft. de Buenos Aires*, 1946, v. 21, Jan.-March, p. 52.

The author presents a case of retinal angiosclerosis with arterial hypertension studied with the neuroarteriolar test of Vidal and Damel, neurocapillary

test of Vidal and Malbrán, blood chemistry, and stereoscopic angioscopy. He concludes that phlebosclerosis predominates over arteriosclerosis, and advises a thorough semiological study of all patients with these modern techniques in order to arrive at a correct diagnosis and rational treatment. (Charts, bibliography.) Plinio Montalván.

Levkojeva, E. F. Regeneration of the external ocular membranes after injuries. Its clinical and prognostic significance in ocular perforations. *Vestnik Oft.*, 1946, v. 25, pt. 3, pp. 25-31.

A microscopic examination of 415 enucleated eyes shows that the regenerative process of the sclera and cornea does not take the form of the usual granulation; it has its own picture with characteristic proliferation of typical cellular elements, which morphologically resembles tissue culture in vitro. The dynamics of the process is characterized by great intensity. Under unfavorable conditions it leads to excessive proliferation, with a tendency of the proliferating tissues to penetrate into the inner structures of the eyeball. The eyeball represents a closed chamber similar to that used for cultures in vitro, and the experience of histologists should suggest measures for regulating the growth of these proliferating tissues. With excessive regenerative processes an independent process of fibromatosis takes place that differs morphologically from sympathetic ophthalmia, but clinically simulates traumatic iridocyclitis from which it should be differentiated. (3 photomicrographs.) Ray K. Daily.

Lund, Axel. A case of interstitial keratitis after phlegmon of the arm. *Acta Ophth.*, 1941, v. 19, pt. 2, pp. 147-152.

A nurse accidentally pricked her arm with a pin, which was contaminated by vomitus. She developed a phlegmon of the arm, and cultures from the pus showed a growth of proteus bacilli. Six weeks later she developed a conjunctivitis, complicated by mild symptoms of iritis, and an interstitial keratitis with a massive discoid infiltration. The pathogenesis of the ocular disease is discussed, and the author believes that it is analogous to endogenous gonorrheal conjunctivitis. Ray K. Daily.

Lund, Axel. A family with Groenouws hereditary dystrophy of the cornea. *Acta Ophth.*, 1941, v. 19, pt. 2, pp. 153-161.

Lund reports a case of the granular type of corneal dystrophy. A chart of the family tree of three generations reveals three affected members in the last two generations. The literature is reviewed. (Genealogical tree.)

Ray K. Daily.

Magitot, A. Pterygium and keratoplasty. *Ann. d'Ocul.*, 1946, v. 179, June, pp. 346-352.

The following operation for potentially recurrent pterygium is considered superior to buccal mucous membrane implants. With a 5 to 6 mm. trephine, one third of the cutting edge of which has been removed, a semilunar incision is made around the head of the pterygium. The cornea is marked to outline a future implant. The pterygium is excised from the cornea and conjunctiva with a keratome-like knife and scissors. At the site of the previous marking with the trephine an incision is made one half way through the cornea. This semicircular piece of cornea is then excised with a sharp cystotome and keratome. A similar piece of cornea is excised from a donor, or from the same

eye. If the graft is secured from a donor, the eye should have been immediately excised unless kept in hemolyzed serum in temperature of four degrees for not more than four to eight days. A conjunctival flap is dissected from above and below and held in place over the graft by two conjunctival sutures.
Chas. A. Bahn.

Pillat, A. Report on the appearance of keratomalacia in Austrian adults. *Wien. klin. Wchnschr.*, 1946, v. 58, pp. 557-560.

Xerophthalmia and keratomalacia, which are caused by deficiencies and insufficiencies in nutrition, were almost unknown in Europe, particularly in agricultural Austria. Before World War II there were only three reports concerning the findings of xerophthalmia in Europeans and these concerned inmates of public institutions. During 1945 and 1946 signs of vitamin A deficiency appeared in the population of Vienna. An increasing number of people had nightblindness (60 percent of all the patients admitted to the Eye Clinic). Prexerosis and Bitot's spots were noted in a smaller percentage of patients. Pillat reports four patients with advanced eye findings. He describes the clinical course in two infants whose eyes had large dry ulcers of the cornea and widespread corneal prexerosis. Two adults also had dry central corneal ulcers with reduction of sight to hand movements and finger counting. The author mentions that the lack of food was also responsible for a more serious course of other eye diseases like serpentic ulcers and for a number of post operative infections after intraocular surgery. He prefers pure cod liver oil to vitamin concentrates for treatment.

Max Hirschfelder.

Strakhov, V. P. Kuhnt's conjunctival flap in corneal perforations. *Vestnik Oft.*, 1945, v. 24, pt. 3, pp. 19-21.

Strakhov believes that the effectiveness of sulfa drugs in preventing infection eliminates the indication for Kuhnt's conjunctival flap, and that its traditional indications need revision.

Ray K. Daily.

Vrolijk, M. Corneoscleral cyst. *Acta Ophth.*, 1941, v. 19, pt. 1, pp. 44-51.

The author adds an eleventh case of congenital epithelial limbal cyst to the literature. The clinical appearance, surgical treatment, and the microscopic appearance of this cyst are described. Theories as to the origin of such cysts are stated. The most probable theory postulates that the cysts originate from vestiges of embryonic veins, which were not completely obliterated, or from capillaries, which missed the connection with the canal of Schlemm.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Azzolini, Umberto. Ossification of the choroid and sympathetic neuroretinitis. *Rassegna Ital. d'Ottal.*, 1941, v. 10, July-Aug., pp. 357-399.

Attention is called to the fact that the term ossification of the choroid is incorrect as the choroid is merely the tissue in which the newformed bone is pathologically developed. At the age of eleven years a girl suffered a penetrating wound of the left eye, which gradually decreased in size and was blind. Eleven years later photophobia and gradually decreasing vision was noted in the right eye. The important change in the sympathizing eye was a neuro-

retinitis, without involvement of the uvea.

An excellent review of the subject of bone formation in various tissues of the eye is given and an extensive bibliography. The author contends that bone develops from an inflammatory exudate which arises from the choroid. (3 figures.)
E. M. Blake.

v. Bahr, Gunnar. The physiologic importance of elimination of aqueous through the cornea. *Acta Ophth.*, 1941, v. 19, pt. 2, pp. 125-134.

The author reviews the literature and reports his investigations on rabbits. The findings confirm Ridley's results on enucleated eyes, and show that there is a normal loss of fluid through the cornea. The layer of lacrimal fluid, exercises an osmotic effect on the aqueous.
Ray K. Daily.

Baltin, M. M. Roentgenographic study of the drainage of aqueous from the anterior chamber. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 14-19.

Thorotrast, used as the contrast material, was injected into the anterior chamber of rabbits. The findings on 40 animals show that the thorotrast is gradually absorbed; it passes from the angle of the anterior chamber into the suprachoroidal space and simultaneously invades the stroma of the iris. Not once, in the 40 experimental animals, was it found to enter Schlemm's canal. Histologic examination of the enucleated eyes confirmed the roentgenoscopic findings. The particles of the contrast substance are carried away by the histiocytes which pass into the suprachoroidal space, and from there probably through the emissaries into Tenon's capsule. The histologic picture demonstrates also the part which the iris plays in the elimination of colloids

from the anterior chamber. It is possible that the route taken by the particles of thorotrast is not the physiologic pathway of drainage since the injection of foreign substances into the anterior chamber creates abnormal conditions. The literature is reviewed.

Ray K. Daily.

Barany, E. Role of ultra-filtration in the formation of aqueous humor. *Nature*, 1946, v. 158, Nov. 9, p. 665.

The present work was undertaken to test the alternative (2) that the amount of sodium entering the aqueous by secretion greatly exceeds the amount entering by ultrafiltration, even if ultrafiltration still supplies a considerable part of the fluid volume of the aqueous.

If the secretion is to supply almost all the sodium and the ultrafiltrate a considerable part of all the fluid, their respective sodium contents obviously must be markedly different. But as sodium is the absolutely dominant cation of the aqueous, a marked difference in osmotic pressure would necessarily accompany any large difference in sodium content. If alternative (2) were true, then the secretion would have a higher osmotic pressure than the ultrafiltrate. The aqueous, being a mixture of the two, would have an intermediate osmotic pressure, and this would depend on the proportions of the mixture. Thus, by reducing the amount of ultrafiltrate, one could change the osmotic pressure of the aqueous towards that of the secretion and, as the secretion is hypertonic, towards higher values of osmotic pressure.

The amount of ultrafiltrate (if any) in the aqueous of one eye was reduced by clamping the homolateral common carotid artery in rabbits. This greatly reduced the filtering pressure and there-

by the rate of ultrafiltration. The osmotic pressure difference between the two aqueous humors was determined by the Hill-Baldes thermo-electric method $1\frac{1}{2}$ to 2 hours after carotid closure. The mean difference between the side with closed carotid and the control side was $-0.5 + 1.1$ mgm. sodium chloride per 100 ML (29 experiments on 22 animals, 3 to 9 determinations of osmotic pressure on each sample). Thus, the blood pressure reduction cannot have augmented the osmotic pressure by more than at most $-0.5 + 3 \times 1.0 = 2.8$ mgm. sodium chloride per 100 ML. This change is so small that ultrafiltration cannot play any considerable part in the formation of aqueous humor.

Theodore M. Shapira.

Costi, C., and Marñón, G. **Uveoparotid fever (Heerfordt's syndrome).** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Dec., pp. 1122-1129. (See Section 17, Systemic diseases and parasites.)

Godtfredsen, Erik. **Chronic iridocyclitis with neurologic symptoms.** Acta Ophth., 1945, v. 27, pt. 1, pp. 75-87.

The material for this first systematic investigation into the simultaneous involvement of the uveal tract and the central nervous system comprises 451 cases of chronic iridocyclitis, nine of which had neurologic symptoms caused chiefly by a transitory arachnoiditis in the posterior cranial fossa. Among the 451 patients 26 had benign lymphogranulomatosis; nine probably did, and the etiology in the others was presumably tuberculosis. Of the nine cases with neurologic symptoms five were diagnosed as benign lymphogranulomatosis, in two the disease was suspected, and two were tuberculous. It is

thus seen that iridocyclitis of benign lymphogranulomatosis presents neurologic symptoms 20 to 40 times more frequently than other forms of iridocyclitis. In all nine the iridocyclitis was bilateral, severe, and lasted from six months to five years. The neurologic symptoms were polymorphous. Unlike the symptoms of the iridocyclitis most of the neurologic symptoms were transitory, except in the patients with tuberculosis, who died, one of meningitis, and the other after a fall due to his cerebral lesion. Two of the nine patients presented Heerfordt's syndrome. The prognosis for the patient with iridocyclitis associated with neurologic symptoms is poor if the etiology is tuberculosis, but is much more favorable if the cause is benign lymphogranulomatosis. (1 table.) Louis Daily, Jr.

Goldmann, H. **Further note on the outflow of aqueous in man.** Ophthalmologica, 1946, v. 112, Dec., pp. 344-349.

Independently of Ascher (Amer. Jour. Ophth., 1942, v. 25, pp. 1174-1209) Goldmann discovered and reported (Ophthalmologica, 1946, v. 111, pp. 146) conjunctival or subconjunctival vessels with clear colorless "cores" and red rims. Upon resumption of communications between Switzerland and the U.S.A. it became clear that these blood vessels were identical with Ascher's aqueous veins. In a number of indirect ways, Ascher has shown that the clear colorless contents of these vessels are in all probability aqueous. Goldmann offers two direct means of proving that the aqueous veins serve as outlets for aqueous. The colorless fluid within these veins can only be plasma or aqueous. Upon intravenous injection of a dye that penetrates poorly into the aqueous, the aqueous vein should re-

main colorless if it contains aqueous, and become stained if it contains plasma. Goldmann has used fluorescein intravenously or by mouth in a number of patients with clearly visible aqueous veins and found that their clear portions remained clear while all conjunctival blood vessels showed greenish-yellow haloes. Another way of demonstrating the function of the aqueous veins has been to inject dilute India ink into the anterior chamber of a human eye with malignant melanoma immediately before the enucleation. A few minutes later the formerly clear portion of an aqueous vein was found to be occupied by stagnant dark fluid while all other conjunctival vessels had retained their normal color. Then there can be no doubt that the clear contents of aqueous veins consist of aqueous.

Peter C. Kronfeld.

Jona, S. *Angio-sarcoma of the choroid*. *Rassegna Ital. d'Ottal.*, 1914, v. 10, Nov.-Dec., pp. 557-575.

The author discusses the various hypotheses presented as to the histogenesis of tumors of the choroid and describes three cases of leukosarcoma. (4 figures.) Eugene M. Blake.

Katzenellenbogen, I. *Recurrent aphthous ulceration of oral mucous membrane and genitals associated with recurrent hypopyon iritis (Behcet's syndrome)*. *Report of three cases*. *Brit. J. Derm. and Syph.*, 1946, v. 58, July-Aug., pp. 161-172.

Behcet's syndrome consists of aphthous ulceration on the oral mucosa, particularly that of the lower lip, sharp edged ulcers of the scrotum and root of the penis, and hypopyon iritis with hemorrhages in the vitreous and retina. The lesions are recurrent. Two of the patients also suffered from recurrent

erythema nodosum and epididymitis. There is a gradual loss of vision from recurrent hemorrhage. All the patients have a peculiar skin reaction in that wounds from the hypodermic needle are followed by erythema and pustule formation. Smallpox vaccine seems to be the best treatment.

Irwin E. Gaynon.

Loewenstein, A., and Foster, J. *Malignant melanoma of limbus and spontaneous cyst of pigmented layer of iris in same sector*. *Arch. of Ophth.*, 1947, v. 37, Jan., pp. 8-17.

A malignant episcleral melanoma, a spontaneous cyst of the posterior tissue of the iris, and a heavy deposit of pigment in the meshwork behind Schlemm's canal were observed in the same sector of the eye of a woman, 33 years of age, who also had bilateral congenital cataract.

It is suggested that fetal inflammation simultaneously produced the cyst, by preventing complete closure of the cleft between the two layers of the optic vesicle, and the melanoma, by displacement of the pigment-storing cells of the outer germinal layer. The congenital cataract and the heavy pigmentation of the meshwork behind Schlemm's canal probably originated in the same inflammatory process.

R. W. Danielson.

O'Reilly. *Massive choroidal hemorrhage*. *Arch. Chilenos de Oft.*, 1946, v. 2, Jan.-Feb., pp. 23-26.

A patient aged 15 years had an extremely violent pain in the right eye, increasing for five days, with marked redness and complete loss of vision in this eye. Examination showed edema of the lids and of the surrounding adnexa, some exophthalmos with retention of movements, clouding of the cornea, and

moderate shallowness of the anterior chamber. The iris was edematous, the pupil dilated ad maximum, intraocular tension plus three. The preliminary diagnosis was of retinal glioma. The enucleated eye showed massive choroidal hemorrhage with infiltration into the vitreous and retinal detachment. The condition is extremely rare. (2 illustrations.)

W. H. Crisp.

Rubino, A. The uveal-meningitic syndrome. Riv. Oto-Neuro-Oft., 1946, v. 21, March-April, pp. 73-84.

Five cases of this syndrome are reported. Three of the patients were male and their ages ranged between 7 and 64 years. The syndrome consists of a bilateral, acute, exudative choroiditis, or iritis and irido-cyclitis, accompanied by neurologic and general disturbances. The disease starts suddenly, usually with high temperature, headaches, vomiting, delirium, and disturbances of sight which may lead rapidly to blindness. Blepharospasm with intense photophobia and lacrimation are usual symptoms. Conjunctival and pericorneal injections, and a turbid vitreous with intense papillitis and peripapillitis are always found, and some eyes have synechias. The disease lasted from one to three months and showed marked improvement after spinal punctures. Like Harada's and Vogt-Koyanagi's diseases this syndrome is obscure in etiology and pathogenesis. The association of uveal and meningeal symptoms suggests the importance of an embryonic, morphologic, and functional analogy between the uveal membrane and the leptomeninges.

Melchior Lombardo.

The author reports four cases, respectively of recurrent iritis, recurrent hyalitis, episcleritis, and uveitis, all apparently attributed to dental infection, but in none of which the result of attention to the diseased teeth is stated.

W. H. Crisp.

Sathaye, V. D. Iridectomy under a conjunctival flap. Indian Jour. Ophth., 1946, v. 7, April, pp. 25-27.

After preliminary anesthesia, and bridge suture, the author makes a conjunctival flap, and an incision into the sclera just above the limbus from 11 to 1 o'clock which is gradually deepened until the anterior chamber is reached. The iris is then grasped by forceps and excised.

Irwin E. Gaynon.

Scullica, F. The pathologic vascularizations of the anterior surface of the iris. Ann. di Ottal., 1946, v. 73, Feb., pp. 65-90; March, pp. 129-166.

From a mass of clinical and histological observations differential criteria are established for the recognition of three types of pathological vascularization of the iris.

In absolute glaucoma the site of predilection is the ciliary zone of the iris, and the vessels rarely extend further inward than the collarette; only in an advanced stage may a small branch here and there reach the pupillary zone. The vessels for the most part are narrow and their course tends to be parallel to the ciliary margin. Lying at different levels in the stroma they may emerge at any point and then, after a more or less undulatory course on the surface of the iris, reënter the stroma, without diminution of caliber. Sometimes they form a broad festoon with both its ends at the ciliary margin. Their branches, if any, are almost always terminal, but usually they do not

Sánchez H., J. R. Dental focal infection. Bol. del Hosp. Oft. de Nra. Sra. de la Luz, 1946, May-June, pp. 179-184.

give off collaterals or form networks. Occasionally they may have radial branches extending to the collarette where they may bifurcate.

In iridocyclitis the vessels for the most part have a radial course and are quite stout and tortuous, with frequent subdivisions and anastomoses. They usually originate at the periphery and tend to form networks of increasing compactness as they approach the pupillary margin. The sphincteric zone is always involved, and vessels may extend into the pupillary area with the formation of new connective tissue. Recognition of this type is facilitated by the presence of synechiae or a pupillary membrane or by the behavior of the uveal pigment.

In rubeosis the vascularization differs appreciably from that found in the other two types. Its site is by preference in the sphincteric zone; less commonly, in proximity to the ciliary margin. The vessels may be so small as to escape detection unless the slit-lamp is used; they typically take the form of fine networks or clusters, either isolated or connected by slender branches. One or two larger vessels, rarely as many as four, may extend outward in a radial direction. Partial ectropion of the uvea may also be present.

All three types are associated with glaucoma. In absolute glaucoma and typically in rubeosis the glaucomatous state precedes the vascularization, whereas the reverse is true in iridocyclitis.

In all three types, though less so in rubeosis, the anterior chamber is abnormally deep. (In most cases of absolute glaucoma there is no vascularization and the anterior chamber is not deep.) It is possible that the cause of the increased depth is to be found in the

marked venous stasis and consequent transudation.

In all three types the action of miotics is prejudicial. Mydriatics act beneficially by combating the venous stasis in the iris. Harry K. Messenger.

Sironi, L. *Frequency of tuberculosis of the eye and its treatment with tuberculin*. *Rassegna Ital. d'Ottal.*, 1942, v. 11, Jan.-Feb., p. 37.

Sironi gives an excellent survey of the opinions of various authors as to the frequency of tuberculosis as the cause of ocular disease. For instance, tuberculosis is believed to be the cause of all choroiditis by Courfein and of 20 percent of it by Uhtoff. Twenty cases of fundus disease are reported in detail, including exudative choroiditis, conglomerate tubercle, retinal hemorrhage, neuroretinitis, and periphlebitis. The skin reactions, vision, recurrence after treatment with tuberculin, and dosage of tuberculin are discussed. Five beautiful colored plates are included.

Eugene M. Blake.

Stocker, F. W. *Experimental studies on the blood-aqueous barrier*. *Arch. of Ophth.*, 1946, v. 36, Nov., pp. 612-616.

In order to understand better the abnormal variations of the intraocular pressure, one should know as much as possible about the normal mechanism of the exchange of fluid between the blood and the eye, the rate of inflow of the fluid and how this rate may be changed under various conditions. Several attempts have been made to supply the blood with a tracer substance, the presence of which could be demonstrated in the aqueous after passage through the blood-aqueous barrier. The fluorescein test is a useful method for studying the production and circu-

lation of the aqueous. but there is no accurate way of recording the concentration of fluorescein in the aqueous. Other substances have been used as tracers such as heavy water, and radioactive isotopes of sodium chloride and phosphorus.

A new method of recording fluorescence of the aqueous after intravenous injection of sodium fluorescein, using the Colman photofluorometer, is described. It is demonstrated that the diffusion of fluorescein from the blood into the aqueous of rabbits takes a fairly regular course between three and ten minutes after the injection, after which time it becomes irregularly increased. Further work is to be published soon.

R. W. Danielson.

Tucker, H. A. Penicillin treatment of acute syphilitic nephrosis and iritis. Report of a case. *Am. J. Med. Sc.*, 1946, v. 211, June, pp. 718-722.

A colored woman, 29 years of age, had dimness of vision due to an inflamed, painful right eye, of two weeks duration. After diagnosis had been made of secondary syphilis with nephrosis and acute iritis, the patient was given 600,000 Oxford units of sodium penicillin in 7½ days, which caused immediate and sustained improvement of the eye and of the renal lesion. The syphilitic infection itself was apparently cured 708 days after initiation of treatment. (2 figures, references.)

Bennett W. Muir.

Verhage, J. W. C. Juxtapapillary chorioretinitis (Jensen). *Ophthalmologica*, 1946, v. 111, June, pp. 351-358.

The author quotes Jensen's original description of the chorioretinitis which bears his name as well as van der

Hoeve's theory concerning the pathology of this disease.

A detailed case history is added. A man, 27 years of age, had typical chorioretinitis in his right eye with a striking lesion of a vein and many cholesterol deposits in the fundus. The apparently healthy left eye showed two old periphlebitic patches. The internal examination was negative, except for an increase in the blood cholesterol and an abnormal relationship between the free cholesterol and its esters.

The author believes that tuberculosis is the cause of juvenile retinal periphlebitis as well as of Jensen's chorioretinitis. Both diseases affect young, apparently healthy persons. (3 figures, references.)

Alice R. Deutsch.

Verrey, Florian. The practical importance of intraocular phagocytosis. *Ophthalmologica*, 1946, v. 111, April-May, pp. 222-228.

A systematic study of the cytology of the aqueous is recommended by the author. An exact knowledge of the cell content facilitates adequate chemical and vaccine treatment and provides the means to enhance the intraocular phagocytosis by appropriate measures. Microphages in the aqueous were found 96 times in 500 smears. An extraocular focus of infection, sometimes in combination with tuberculosis or syphilis was found in half of the cases. Three clinical histories are recorded as illustrations. (2 tables, 8 figures, references.)

Alice R. Deutsch.

Vidal, F., and Damel, C. S. The ocular neurovegetative system: blue eyes and brown eyes. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 593.

The authors investigated the myd-

riatic action of sympathomimetic drugs instilled in the eyes of 200 individuals of different sex and age. This investigation showed that mydriasis was greater in light colored eyes, even when the drug was used in weak concentration. The blue irides showed the maximal pupillary dilatation, with green, greenish-brown and brown following in decreasing degree of dilatation. The action of sympathomimetic drugs is very slight in dark brown eyes. In heterochromia the dilatation is very marked in the lighter colored eye. When neurovegetative dystonia is present the mydriatic action of the drug is evident, regardless of the color of the iris.

Amat, M. M. The mechanism of action of antiglaucomatous operations. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Jan., pp. 69-81.

An exhaustive review of the literature and brief consideration of several of the author's clinical experiences lead him to the conclusion that all antiglaucomatous operations have a common mode of action; namely, they act directly on the ciliary body by modifying its innervation or vascularization, and indirectly on the eyeball. A new relation is thus established between the secretion and circulation of the intraocular fluids. The operations are actually arteriectomies and sympathectomies.

Barrio, A. The pathogenesis and medical therapy of acute inflammatory

glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Aug., pp. 676-692.

After an exhaustive review of the literature the author concludes that glaucoma is a symptom complex, the outstanding feature of which is the increased ocular tension, and the causes of which may be many, just as the causes of edema may be many. Barrio agrees with Terson that glaucoma is a localized edema. Diagnosis should be directed towards discovering the cause of the increased vascular permeability, be it a vegetative neurosis, an endocrine disturbance, intoxication, infection, allergy, or local or general vascular disease. The early stages of hypertension are practically always due to an increased capillary permeability, and it is only during this period that medical therapy can be effective. Diminution of the capillary permeability can be attained by etiologic treatment and by drugs that act directly on the vessels, such as iron oxide and calcium. Salicylates, antipyrin, and pyramidon also have been found to reduce capillary permeability. The effectiveness of the administration of antihistaminic agents, such as the biologic amines, and of histamine desensitization are being investigated.

Bolgov, P. J. Chiazzaro operation in glaucoma. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 77-83.

This is a detailed report of the implantation of magnesium into the anterior chamber in 39 eyes with glaucoma, which was absolute in all but ten. A conjunctival flap was made as in Elliott's trephine operation, a linear incision was made at the limbus, and a strip of metallic magnesium 2 by 4 mm. was partly introduced into the anterior chamber so that one third of it remained under the conjunctiva. Two

eyes developed late infections and were enucleated. The tabulated data show the effectiveness of the operation and Bolgov advocates its inclusion in the list of antiglaucomatous operations. (5 tables.)

Ray K. Daily.

Busacca, A. What have we learned about gonioscopy? *Ann. d'Ocul.*, 1946, v. 179, Aug., pp. 415-432.

After a historical and anatomical review the author states that gonioscopic synechias are not the expression of a specific pathologic process, but are evidences of different inflammatory processes which are first visible around the iridocorneal sinus. In uveitis with ocular hypertension the author has not observed any pathognomonic sign. Blood vessels do not normally exist in the region of the iridocorneal sinus though in severe uveitis a form of posterior pannus may be seen. After a very detailed study of 25 glaucoma patients and a less detailed gonioscopic study of many more, the author is convinced that there is in the iridocorneal sinus of the glaucomatous no sign characteristic and pathognomonic of glaucoma. The classification of glaucoma into wide and narrow angle types is of little practical value because although the scleral wall of the mouth of the irido-corneal sinus is fixed, the ciliary and iris walls are mobile and with their movements they modify the position of the angle and depth of the iridocorneal sinus. Sclerosis of the trabeculae is not visible gonioscopically. Salzmann showed in 1915 that mydriatics do not close the iridocorneal sinus but, on the contrary, facilitate its examination. Atropine and other cycloplegics do not cause mechanical blockage by pressing the iris against the wall of the irido-corneal sinus. Experimentally, eserine narrows the iridocorneal sinus which is widened

by atropine. Gonioscopy does demonstrate, however, that the iridocorneal sinus and the Canal of Schlemm play a very insignificant part in the production of glaucoma. (20 figures.)

Carreras Matas, B. Diagnosis of glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Dec., pp. 1093-1096.

There are three important signs of glaucoma, ocular hypertension, atrophy with excavation of the disk, and alteration the field of vision. Sometimes simple glaucoma is suspected but one should never dare to make a diagnosis unless one of the cardinal symptoms is present.

J. Wesley McKinney.

Casero, L. The association of nevus flammeus, glaucoma and Weber's syndrome. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, April, pp. 370-383.

A nine-year-old girl had a nevus flammeus in the region of the distribution of the first branch of the trigeminal nerve on the left side. The intraocular pressure was 60 mm. of Hg in the left eye. It was reduced to 45 mm. by pilocarpine, and maintained at that level for one year. She had an excavation of the optic disc, normal peripheral fields, and a central scotoma. Neurologic examination revealed a reduction in auditory acuity, bilateral disturbances in the pyramidal tracts, a left hemiparesis, and slight mental retardation. Radiography demonstrated a dilatation of the diploic venous sinuses of the left frontal region, and small calcifications above the alae of the sphenoid. The literature is briefly reviewed.

Ray K. Daily.

Dalsgaard-Nielsen, Esther. Buphthalmia. (A survey of buphthalmic patients admitted to the eye clinic of the

Rigshospital in the period of 1910-1943.) *Acta Ophth.*, 1945, v. 23, pt. 1, pp. 49-74.

The 49 patients found in this survey comprise 0.32 percent of the eye patients. In 35 percent the disease was unilateral. In 44 percent the diagnosis was made at birth, and in 38 percent within the first six months of life. One half of the patients were treated in their first year, and 20 percent under the age of three years. The material includes two families in which the disease was hereditary. The corneal diameter of the affected eyes ranged from 10.5 to 17 mm., with an average of 13.6 mm. Intraocular tension varied from 28 to 101 mm. Hg. and usually was between 40 and 70. Seven eyes were treated with pilocarpine. Seventy-four eyes were operated upon from one to six times, a total of 137 operations. The operation most commonly employed was Elliott's trepanation. Postoperative improvement was noted in 83 percent of the surgical patients. For 32 patients the period of observation ranged from 1 to 25 years. Many were observed for 10 years, and data on vision were available for 47 eyes. Of these 6 were enucleated, and 10 were blind; 10 eyes had less than 5/60 vision, 7 less than 6/24, and 8 had a visual acuity between 6/18 and 6/6. The value of early operation is evident from the fact that most of the patients with good vision were among those on whom the operation was performed within the first year of life. (9 tables.)

Louis Daily, Jr.

Dominguez, D. D., and Lucena, M. de T. **Glaucoma and the vegetative system.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 865-870.

The data of the authors' investigations of the general state of the autonomic nervous system in glaucoma

show that 65 percent of patients with inflammatory glaucoma are amphotonic, and that patients with simple glaucoma suffer from dystonias of a mixed type. The local autonomic innervation was dystonic and with a constant increase in sympathetic excitability. As long as glaucoma remains in the phase of neurosis general medical therapy may regulate the general and local vegetative tone with arrest of the disease. The diagnosis must be made early, before local organic changes develop.

Duran, C. B. **Can glaucoma be an occasional cause of death?** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Jan., pp. 21-25.

Two cases are reported, in which glaucoma is considered the cause of death. The first occurred in a hypertensive, plethoric woman, who came for an eye consultation immediately after a heavy meal. After a diagnosis of preglaucoma she became excited, and developed an acute attack of glaucoma with severe headache and vomiting, which was followed in a few minutes by fatal apoplexy.

The second patient bled to death after a few days of uncontrollable hemorrhage that followed the enucleation of a hard, staphylomatous blind eye.

Epstein, E. **Report on a case of hydrophthalmia (Buphthalmos).** *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 476-478.

A soldier, 24 years of age, served through five years of battles without ocular symptoms. When he complained of headache his vision was found to be 6/60 and 6/18, corrected to 6/36 and 6/9. Shortly thereafter he developed absolute glaucoma in the right eye.

Both corneas were large; the corneal diameters were 14 and 13.5 mm., and the radius of curvature was 7.5 and 7.0 mm. in the right and left eye respectively. It was assumed that the megalo-cornea was an example of arrested hydrophthmia which had suddenly become "decompensated."

Morris Kaplan.

Fialho (Sylvio), Abreu. **Heredity in glaucoma.** *Rev. Brasileira de Oft.*, 1946, v. 5, Sept., pp. 17-25.

The author cites two family histories, the former of which is thought to illustrate the rule of anticipation laid down by Albrecht Graefe, according to whom familial glaucoma appears with increasing precocity in successive generations of the same family. The second family tree recorded by Fialho shows glaucoma in three successive generations and, in a prodromal stage, in at least two members of the fourth generation. Grigorieva, H. I. **Experimental cyclodialysis on rabbits, with Heine and Zalman's technic.** *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 70-73.

The right eyes of six rabbits were operated upon by Zalman's technic and the left by Heine's. At various intervals after the operation a dye was injected into the anterior chamber, and shortly afterward the eyeballs were enucleated

and examined microscopically. The detailed protocols of the eyes reveal that in none of the eyes was the dye found in the suprachoroidal space. Detachment of the ciliary body was found in nine eyes; in one right and in two left eyes the ciliary body was in contact with the sclera. Hemorrhage into the anterior chamber was found in three right eyes and one left. Hemorrhage into the ciliary processes was present in five right and two left eyes; apparently such hemorrhages become absorbed slowly, for they were found in eyes enucleated 20 days after the operation. Perhaps the failure of some of the operations was caused by hemorrhage that blocked the drainage from the anterior chamber. There is no indication that the trephine opening has any significant advantage over the scleral incision, although it is closed by a less dense fibrous tissue than that which unites the scleral incision.

Hibbeler, H. L. **Personality patterns of white adults with primary glaucoma.** *Amer. Jour. Ophth.*, 1947, v. 30, Feb., pp. 181-186. (2 tables, 4 charts, references.)

Hughes, W. L., and Cole, J. G. **Technical uses of air in ophthalmology.** *Trans. Amer. Ophth. Soc.*, 1945, v. 43, pp. 115-135.

The authors review the uses of air in ophthalmologic radiography and surgery. Surgical experimentation on laboratory animals employing air goniotomy led to the adoption of a surgical technique by which it is possible for them to perform goniotomy in eyes with glaucoma with a shallow anterior chamber as well as those with a wide angle. By simply increasing the amount of air in the anterior chamber its depth

may be increased. They further demonstrated that a very distinct view of the anterior chamber can be obtained by substituting air for the aqueous, which makes a contact glass unnecessary in performing goniotomy. The authors have designed a goniotomy knife with a hollow shaft and an opening near the heel of the blade. By attaching two syringes, a system for withdrawing aqueous and supplanting it with air becomes practical. In three cases of glaucoma such goniotomy was at least temporarily successful.

C. D. F. Jensen.

Ivanov, N. K. Late results of cyclodialysis in glaucoma. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 66-70.

This is an analysis of 100 cases followed from two to eight years. Tension was permanently normalized in 70 percent of chronic inflammatory glaucoma, and in 51 percent of simple glaucoma. Visual acuity remained unchanged in 39 percent of chronic inflammatory glaucoma and in 17 percent of simple. In 26 percent of all cases the eyes became blind, and in 18 percent visual acuity was reduced to light perception because of cataract. Cataract that developed after the operation, particularly with hypotony, was due to a metabolic disturbance in the lens as a consequence of postoperative changes in the ciliary body. Reduction of visual acuity was seen in eyes with normalized tension as a result of progressive cataract or progressive atrophy of the optic nerve. The visual field remained unchanged in 60 percent of cases of chronic inflammatory glaucoma, and in 31 percent of simple glaucoma. The appearance and progression of myopia in emmetropic or hyperopic eyes occurred in 11 percent of cases, and an

increased myopia in myopic eyes in 3 percent. (2 tables.) Ray K. Daily.

Jona, Sergio. The importance of the hypophysis in regulating ocular tonus. *Rassegna Ital. d'Ottal.*, 1941, v. 1, March-April, p. 151.

The author found a hypofunction of the hypophysis in patients with various kinds of glaucoma. Imre examined 50 pregnant women and found a consistent hypotension, but Baratta could not confirm this. Jona describes the changes in the diameter of the pupil and the intraocular tension of rabbits and normal human beings after the injection of five units of vasopressin, a dose not harmful to man. The effect was studied on eyes under the influence of atropine and of eserine. No change was noted in the retinal arterial pressure or the visual fields. Vasopressin in man has a sympathicomimetic action and does not overcome atropine mydriasis, but in rabbits the effect is parasympathicomimetic and abolishes the mydriasis. In both man and rabbits a hypotension is developed, but is less evident in man. Further studies are needed to determine the actual value of this pituitary extract in the treatment of glaucoma. (10 figures.) E. M. Blake.

Kalfa, S. F. The management of increased intraocular tension in war injuries. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 55-58.

The development of secondary glaucoma following eye injuries is frequently overlooked. For an adherent leucoma the most effective surgical procedure is the double iridectomy proposed by Filatov. Two corneal incisions, made by the puncture and counterpuncture of a Graefe knife, or ab externo, and two iridectomies per-

mit complete separation of the anterior synechia, and restore normal conditions in the anterior chamber angle. Delayed restoration of the anterior chamber if not due to a fistulating wound is treated by a posterior sclerectomy with evacuation of a bead of vitreous. Secondary glaucoma in an aphacic eye is treated by cyclodialysis, through a small trephine opening in the sclera. Rise of ocular tension, caused by uveitis is controlled by alternation of miotics and mydriatics, by osmotherapy, and by retrobulbar injections of novocain. Fuchs's transfixion of the iris is performed for iris bombe, and in cases where this procedure fails it is followed by an iridectomy.

Ray K. Daily.

Kashuk, M. E. **Elastotonometric studies in hypertension.** *Oftal. Jour.* (Odessa),: 1945, pt. 2, pp. 9-15.

By means of elastotometry Kalfa demonstrated that ocular tension is regulated by an intraocular vascular reflex. The stimulus to this reflex is variation in the intraocular vascular pressure, which is dependent on the general vascular pressure. Each rise in the general blood pressure leads to the simultaneous rise in the ocular tension, which promptly returns to its original level through the function of the regulating vascular apparatus. In the early stages of hypertension the lability of the blood pressure makes repeated demands on the intraocular vascular reflex which is compelled to compensate for frequent and sharp variations in blood pressure. As a result the sensitivity of this reflex is increased. This can be demonstrated by the method of elastotometry which consists of measurement of the tension with the tonometer with four different weights.

In normal eyes the data when plotted, form a straight curve 10 to 12 mm. high. In hypertensive patients the curve is shorter and broken. Kashuk tabulates the measurements of 60 normal eyes in patients with general hypertension and illustrates the changes in the elastotonometric curve. Data show that the elastotonometric curve in 39.1 percent of these patients was 7.1 mm. shorter than the normal curve and sometimes also broken, and that the average rise of the elastotonometric curve in hypertensive patients is considerably lower than normal. It is believed that the shortening of the curve is due to the increased sensitivity of the local vascular reflex, and it is pointed out that the normal ocular tension of these eyes supports the generally accepted view that there is no relation between high blood pressure and glaucoma.

Ray K. Daily.

Leopold, I., and Comroe, J. **Use of diisopropyl fluorophosphate ("DFP") in treatment of glaucoma.** *Arch. of Ophth.*, 1946, v. 35, July, pp. 1-16.

The authors report in detail their experience and research in the use of this new drug on fifty patients. Koelle had previously determined that it is stable in peanut oil but not in aqueous solutions.

Diisopropyl fluorophosphate ("DFP") is an anticholinesterase agent capable of producing prolonged and marked parasympathomimetic effects in the eye. "DFP" has successfully lowered intraocular tension in glaucomatous eyes in 0.05 or 0.1 percent concentration in a peanut oil vehicle. In the majority of the glaucomatous eyes treated with 0.05 or 0.1 percent oily solutions of "DFP" the intraocular tension was controlled with decidedly

fewer daily instillations than when either 1-percent pilocarpine nitrate and/or 0.25 to 0.5 percent physostigmine salicylate in water was employed. In all glaucomatous eyes successfully treated with pilocarpine or physostigmine "DFP" was also effective and usually maintained the intraocular pressure at a lower level.

No instance of dermatitis or conjunctivitis due to repeated use of "DFP" was encountered in the 78 patients. In 36 of the 78 glaucomatous eyes in which treatment with pilocarpine or physostigmine had previously failed, "DFP" succeeded in maintaining intraocular tension below 30 mm. of mercury.

"DFP" has several untoward and undesirable ocular effects, namely, visual blurring, brow ache and eye ache, spasm of accommodation, and pericorneal injection. Two eyes showed an increase in tension. (References.)

R. W. Danielson.

Levina, L. S. **The mechanism of raised intraocular tension.** Vestnik Oft., 1945, v. 24, pts. 1-2, pp. 19-21.

The objective of this investigation was to determine the state of capillary permeability in glaucoma. In one group of patients Eppinger's test was used which consists of a 30-minute compression of the hand under a pressure of 40 mm. of Hg. Under normal vascular conditions pressure does not cause a flow of plasma into the tissues, until it is raised to 60 to 80 mm. of Hg. The number of erythrocytes in the blood taken before and after the removal of the pressure indicated changes in the blood concentration. Acceleration of the sedimentation rate indicates a loss of albumen from the blood into the tissues and is regarded as a sign of increased capillary permeability. A

change in the relation between the solid and liquid elements of the blood before and after compression of the hand also indicates a change in capillary permeability. In a third group of glaucoma patients a cantharides blister was produced, and its albumen content analyzed fractionally and compared with a similar examination of the blood. The tabulated data of these tests lead to the conclusion that glaucoma patients have an increased capillary permeability. The increased capillary permeability leads to a disturbance in the osmotic pressure, handicaps the flow of fluid from the anterior chamber, and leads to increased intraocular pressure. The increased intraocular pressure compresses the ocular veins at their point of exit from the eye and further increases the capillary permeability of the veins. The capillary wall also regulates the exchange of gases. A layer of fluid containing an excess of albumen between the capillaries and the tissues leads to a diminution of oxygen and an accumulation of carbon dioxide. The inadequacy of the oxygen supply probably accounts for the progressive loss of vision in eyes which have been operated on successfully for glaucoma. (2 tables.) Ray K. Daily.

Lijó Pavía, J. **Provoked double retinal pulse; sign of preglaucoma?** Rev. Oto-Neuro-Oft., 1946, v. 21, May-June, pp. 47-51.

The author presents four patients with a mild increase in intraocular tension (32 to 38 mm. Hg). Using the ophthalmodynamometer to produce pressure on the eyeball, the usual venous pulse became associated with a retinal arterial pulsation. It is not claimed that this phenomenon may be interpreted as diagnostic of preglaucoma. (1 cinematograph.) Edward Saskin.

Magitot, A. *Lectures on glaucoma*. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Nov., pp. 1000-1013.

This is a digest of four lectures given by Magitot. He emphasized the importance of not confusing hypertension and glaucoma, although to many ophthalmologists these two terms are synonymous. The etiology of glaucoma is discussed, and a critical analysis is made of the symptoms considered typical of glaucoma. Magitot demonstrates that corneal edema and shallowness of the anterior chamber are not direct results of hypertension; that a Bjerrum scotoma is not diagnostic of glaucoma, that in glaucoma it is the minimum separabile and not the minimum visibile that is affected, and that disturbances of color vision and excavation of the optic disc are not dependent upon hypertension. The importance of local vascular disturbances and of the instability of the neuro-vegetative system in the pathogenesis of glaucoma are emphasized. He divides glaucoma into two types; that which appears in hyperirritability of the thalamus; and that which appears in the course of infectious diseases, which lower the psychic and physical resistance. He is logically sceptical of the indications for surgery in glaucoma, and believes that the disease can be controlled by local and general medical and psychic therapy. He also discusses infantile glaucoma and glaucoma without hypertension. Magitot had the opportunity to do a histopathologic examination of an eye with infantile glaucoma in an infant 1½ months of age, who died on the operating table. The examination revealed a buphthalmic eye, with a small lens, and diffuse intraocular and intraorbital vascularitis, similar to that found in syphilis. Like Charlin and Terrien, Magitot considers infantile glaucoma luetic, and

describes a patient in whom infantile glaucoma responded to antiluetic therapy. In general Magitot is a proponent of medical rather than surgical therapy of glaucoma and considers the retinal arterial tension the best guide in the choice of therapy. If the ocular tension is moderately high, and the arterial pressure normal or elevated medical therapy is indicated. A low arterial pressure is an indication for surgery.

Ray K. Daily.

Magitot, A. *Puncture of the anterior chamber*. Ann. d'Ocul., 1946, v. 179, March, pp. 159-163.

After paracentesis the initial decrease in ocular tension is followed by a secondary increase, which may be used as a provocative test in doubtful glaucomas. A positive Kahn reaction as well as tests for urotropin may be obtained from the reformed aqueous of persons in whom the same test made from the primary aqueous was negative. The reformed aqueous contains a higher concentration of serum albumins and globulins as well as of antibodies. Temporary improvement has often followed repeated paracentesis in primary optic atrophy and in chorioretinitis. The transient functional improvement was apparently due to retinal vascular hyperemia induced by the sudden reduction of intraocular tension. In some types of keratitis and uveitis repeated drainage of the aqueous may be of signal service especially at the most critical stages. A paracentesis wound ordinarily is covered by epithelial cells in 60 minutes.

Chas. A. Bahn.

Meyer, Otto. *Inflammatory jugular phlebostenosis as the cause of glaucoma exogenicum*. Brit. Jour. Ophth., 1946, v. 30, Nov., pp. 682-688.

Glaucoma exogenicum is a secondary glaucoma with an extraocular cause. This cause was traced by the author to an endophlebitis of the jugular veins. This phlebitis narrows the lumen of the vein and causes a damning back of drainage of the episcleral vessels. Glaucoma results. Chronic septic conditions of the mouth, teeth, and throat are blamed for this venous infection. The treatment of the glaucoma resolves itself into a recalibration of the jugular veins. Morris Kaplan.

Missiroli, Giuseppe. The behavior of the ocular tension after surgical procedures in the abdomen. *Boll. d'Ocul.*, 1945, v. 24, April-June, pp. 137-151.

The writer examined the changes in the tension in 59 patients for abdominal surgery. A lowering of tension was noted after severe operations and in patients in bad general condition. The hypotony disappeared when the general condition improved and increased still more in those whose condition became worse. The tension is useful in prognosis. (Bibliography.)

Melchior Lombardo.

Moreu, Angel. Surgical indications in glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 859-865.

The objective of every surgical procedure on glaucomatous eyes is to provide intraocular drainage, and to modify the ocular circulation. The first is achieved without difficulty; the other is difficult to achieve and is the principal cause of surgical failure. The operative indication in the preglaucomatous stage is persistence of irregularities in the tension curve, rapid appearance of fluorescein in the aqueous, aggravation of hemeralopia, persistence of pupillary disturbances, and increasing field defects. The operation of choice at this

stage is cyclodialysis, which modifies favorably the iridociliary circulation by eliminating the function of a part of the ciliary body after setting up an aseptic iridocyclitis.

In chronic simple glaucoma the problem is one of inadequacy of intraocular drainage. If the fluorescein and nicotinic acid tests indicate an ineffectiveness of medical therapy, surgery should be resorted to without delay. Progressive loss of central visual acuity, constriction of the visual field, persistence of scotomas, deepening of the papillary excavation, and persistence of raised intraocular pressure are indications for surgery. Gonioscopic examination is of great importance in making the choice of the operation and in selecting the operative site. Vascular sclerosis in the retina and choroid is a contraindication to surgery. Advanced constriction of the visual fields is not as dangerous. Since most of these patients seek advice in an advanced stage of the disease a fistulating operation must be done. Cyclodialysis is effective only in aphacic glaucoma, or as a preliminary to a fistulating operation.

Chronic inflammatory glaucoma calls for a careful determination of the tension curve, the state of the refractive media, and the state of the pupil; if medical therapy does not normalize these processes the patient should be operated upon without delay by a fistulating operation if the inflammatory process subsides, or by an iridectomy ab externo if the congestion persists.

Acute glaucoma should be treated intensively medically, but if the eye does not respond to treatment an iridectomy ab externo should be done within 24 hours. Malignant or hemorrhagic glaucoma reacts unfavorably to surgery, and if it becomes unavoidable Vogt's cyclodiathermy or gonioscyclodiather-

my is indicated. The same procedures may be tried in absolute glaucoma, in the hope of avoiding enucleation.

Ray K. Daily.

Moreu, Angel. **Studies of intraocular vascular permeability in the various phases of glaucoma.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Aug., pp. 636-664.

The author regards vascular permeability as the most important factor in the genesis of glaucoma, and places great reliance on the information obtained from the fluorescein and nicotinic acid tests. He considers these tests imperative in the postoperative follow-up, and warns against neglect of medical therapy and against unjustified reliance on surgical normalization of tension. Medical postoperative therapy should be directed towards the improvement of the intraocular vascular circulation. Normal retinal arterial and venous pressures, with a normal relation to the pressure at the arm are good prognostic signs, whether therapy be medical, or surgical, or combined. Postoperative gonioscopic studies permit the inspection of the ciliary region in the area of the iridectomy or of the cyclodialysis. Edema of the ciliary processes that are more or less covered with a fine exudate and delayed elimination of fluorescein at the angle of the anterior chamber are signs of persistent circulatory stasis. If the circulatory disturbances continue, and venous obstruction develops, the atrophy of the optic nerve will progress, and blindness will result in spite of normal ocular tension.

Ray K. Daily.

Moreu, Angel. **The etiopathogenesis of glaucoma.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, Aug., pp. 729-821.

This very exhaustive dissertation consists of a thorough review of the literature and a report of the author's investigations into many phases of the subject. His clinical material consisted of 543 cases, 537 of which occurred in people over fifty years of age. Age apparently is a significant etiologic factor, and it is in advanced age that circulatory disturbances, which Moreu considers the basic cause of glaucoma become frequent. Acute and inflammatory glaucoma is more frequent among women, whereas simple chronic glaucoma is predominant among men. A large percentage of glaucoma patients are hypermetropic. A small eyeball makes circulation more difficult and the metabolism of a hypermetropic eye is slower than that of a normal eye. This is shown by a slightly subnormal visual acuity in spite of a perfect refractive correction, by reduced light sensitivity and delayed adaptation, and by a retarded retinal chronaxia. The author does not believe that astigmatism is a factor of significance. Seasonal or climatic influences are factors only in the sense that they may precipitate acute attacks. Among the author's patients 482 had vascular diseases. An allergic attack in a glaucomatous person may precipitate an acute attack of glaucoma, but allergy does not cause glaucoma.

Pathologic studies indicate that glaucoma is primarily a disease of the uvea. The author found the angle of the anterior chamber open in all eyes with recent glaucoma. Obstruction is an indication of an advanced stage. He was never able to confirm Barkan's findings of sclerosis of the walls of Schlemm's canal, nor of trabecular flakes. No anatomic lesion, either in Schlemm's canal or in the trabeculae, can explain the genesis of glaucoma, and the author is convinced that the abnormality is in

the root of the iris and in the ciliary body. In these tissues there is evidence of circulatory stasis; when the angle of the anterior chamber is found closed, it is closed by uveal tissue. The cornea and sclera play a passive role.

The changes in the iris, are undoubtedly characteristic of glaucomatous disturbances. The parenchyma has a definite tendency to atrophy and to pigmentary changes. The pupillary reactions are slow, and there is a tendency to mydriasis. The ciliary body, observed gonioscopically, is edematous, and in iridectomized patients the edema can be seen to involve the ciliary processes. The choroid shows signs of circulatory disturbances, and with infrared light one can see atrophic areas, not demonstrable with ordinary illumination. The retinal disturbances, such as hemeralopia and visual field restrictions are due to lesions of the choroid. In incipient glaucoma the optic nerve is not involved, and excavation of the optic disc appears only in advanced stages of the disease. Among the experimental studies recorded is the author's attempt to produce hypertension in dogs by hyperglycemia. Hyperglycemia to the extent of producing coma and death did not produce any significant changes in the intraocular tension. It was also impossible to produce ocular hypertension by the intraarterial injection of drugs that raise the blood pressure. The intraocular pressure appears to remain independent of the general blood pressure. To demonstrate the role of Schlemm's canal the author injected india ink into the anterior chambers of dogs; at the end of four or five days the anterior chambers appeared clear; at this period the animal was killed and the eyes enucleated. Grains of india ink were found in the perivenous spaces, in Blesing's spaces, and in the perichoroidal

space: the canal of Schlemm's and the trabecular spaces were entirely free of the granules, indicating that the dye was not eliminated through these passages. The author believes that Schlemm's canal acts as a protective valve, providing filtration only in cases of increased intraocular pressure. To clarify the role of intracranial pressure in the genesis of intraocular hypertension the author induced intracranial hypotension by drainage of the lateral ventricles. This never led to atrophy of the optic nerve. After high ligation of the carotid artery or the jugular vein optic atrophy developed rapidly, indicating the pathogenic role of a circulatory disturbance. The author concludes that glaucoma develops because an initial neurovegetative dystonia causes a circulatory disturbance in the uveal vessels, as a result of which oscillations in the ocular tension are produced. The result of the persistent circulatory disturbance is a venous stasis that leads to increased capillary permeability and production of albuminous exudates, which block the drainage outlets. Schlemm's canal begins to function as a drainage safety valve and signs of hypertension appear. Nutritional disturbances follow, with inadequate production within the tissues of local vasoregulatory hormones. Further alterations in the intraocular pressure follow, with inadequate nutrition of the optic nerve, and with atrophic excavation. The author emphasizes that hypertension and glaucoma must not be confused. Hypertension must be regarded as one of the symptoms of glaucoma. Glaucoma must be recognized and treated as a primary vascular disturbance, with initial functional ocular changes that are followed by irreversible organic pathologic processes.

Moreu, Angel. The value of pupillography in the preglaucomatous state. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., pp. 743-758.

Moreu's study is made with the Hess and Sander pupilloscopes, and he demonstrates that pupillography can be used to diagnose the functional adequacy of the local sympathetic and parasympathetic innervation. The pupillary reaction has three phases. A primary rapid phase under the influence of the parasympathetic; a second slower phase dependent on a relaxation of the sympathetic, and a third still slower period under the dominance of the sympathetic. Pupillographs taken after the instillation of parasympathetic and sympathicomimetic drugs demonstrate the functional adequacy of the local autonomic fibers. Pupillographic tracings illustrate the various pathologic states of the ocular organo-vegetative apparatus, such as sympathetic hyperirritability, hypoirritability and paralysis and similar states of the parasympathetic. The differential diagnosis of the various pupillary syndromes is described in detail. The author believes that this method affords diagnostic, prognostic, and therapeutic indications, and affords a means of determining the efficacy or failure of therapeutic procedures. (8 graphs.)

Orzalesi, F. Postoperative abolition of the anterior chamber—causes, consequences, remedies. *Ann. di Ottal.*, 1946, v. 73, March, pp. 167-182.

Orzalesi believes that obliteration of the anterior chamber and detachment of the choroid, which frequently occur after Elliot's trephining, are due to an excess of filtration and especially of diffusion beyond the limits of the flap. To prevent excessive diffusion he rec-

ommends preparing the flap in such a way as to have it bounded by a cicatricial line which will serve as a watertight barrier. He prefers Elliot's original triangular flap which has its apex 10 to 12 mm. from the limbus, which forms the base. The entire flap is dissected down to the limbus and is fastened by a single suture at the apex simply to keep it from being displaced by movement of the lids during the first few hours after operation. Since the conjunctiva retracts a little there is a narrow band of exposed sclera along the two sides. In the process of healing this becomes bridged by conjunctival epithelium without the interposition of a layer of subconjunctival tissue, and beyond this line the aqueous cannot pass. In this way a filtering cicatrix quickly forms under the flap. If the tension rises unduly in the process of healing he resorts to massage (but only when the anterior chamber has reformed). If the cicatrix becomes blocked, without other complications, he attempts to open it by cautiously freeing the conjunctiva.

Parker, A. E. P. Bilateral detachment of the choroid of unusual duration following corneo-scleral trephine. *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 595-600.

In a woman, 56 years of age, with bilateral glaucoma simplex corneo-scleral trephining was followed by choroidal detachment in the upper nasal quadrant which persisted for a year before reattachment. A similar detachment in the other eye persisted for six months before recovery. (6 figures.)

Morris Kaplan.

Rønne, Gerhard. Penicillin treatment of late infection following fistulating

operations. *Ophthalmologica*, 1946, v. 111, Jan., pp. 1-7.

Four patients with late infection after a fistulating operation were given penicillin. In all of them the eye was preserved and in only one whose eye had been previously badly damaged did the eye lose its function. Moreover, in this case penicillin was administered intraocularly. In two the penicillin was injected subconjunctivally and was instilled and in one instillation alone was used. The subconjunctival injection of 4000 units of penicillin gives no complications at all. Treatment is very effective, all signs of inflammation disappear almost completely within 24 hours after injection. The author recommends the injection of 5000 units of penicillin subconjunctivally outside the infiltrated conjunctival area and instillations every 15 minutes during the first 24 hours. (References.) Scheglova, A. A. The effect of a fall in barometric pressure on the intraocular tension. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 21-28.

This study was made in the pressure chamber. The tabulated data show that lowered barometric pressure does not affect the ocular tension of the normal eye. A height of 2,000 to 3,000 meters does not affect the tension of eyes with compensated glaucoma but may prove dangerous to eyes with uncompensated glaucoma. The oscillations in ocular tension, under the influence of lowered barometric pressure may prove dangerous even to eyes with a tendency to increased intraocular pressure, especially in persons with disturbances in the cardiovascular and neurovegetative systems and in those with vascular hypertension. Sedan, J. Disc reimplantation after Elliot sclerectomy with cyclodialysis. *Ann. d'Ocul.*, 1946, v. 179, Aug., pp. 433-437.

Cyclodialysis is considered the glaucoma operation of choice in uveal disease. An Elliot trephine type of sclerectomy is made about 3 mm. posterior to the limbus. Elschmig's spatula is introduced in the trephine opening, passed through the suprachoroidal space and into the anterior chamber; it is then rotated about 45 degrees and withdrawn. The scleral disc is replaced in its original site and covered with a conjunctival flap. This technique is believed to minimize infection and other complications. Chas. A. Bahn.

Streiff, E. B. Generalized angiotrophoneurosis and glaucoma. *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 68-73.

A patient was observed in whom a diffuse angiotrophoneurosis was associated with extensive skin lesions and a bilateral glaucoma. A severe imbalance of the neuro-endocrinologic equilibrium was thought to be the origin of both the skin and the eye-changes. (3 figures, references.) Alice Deutsch.

Weekers, L. and R. Treatment of glaucoma by non-perforating cyclo-diathermy. *Bull. Soc. Belge d'Ophth.*, 1945, no. 81, April 29, pp. 50-63.

After experimental and clinical trial with non-perforating cyclo-diathermy, the authors feel that it has a very beneficial hypotensive action in the treatment of glaucoma. The effect is prin-

cipally that of uveal vasodilatation which modifies the aqueous humor and favors its absorption. Later there is a certain degree of atrophy of the ciliary body, which diminishes the production of aqueous and further lowers the ocular tension. In cases of chronic or sub-acute glaucoma, he has found it possible to lower the ocular tension to physiologic level after one procedure. If necessary, it is possible to augment the hypotensive effect by repeating the procedure after a suitable interval. Acute glaucoma, however, does not respond to this form of treatment. In secondary glaucoma and in chronic simple glaucoma the reduction in tension is less, but the procedure is sufficiently effective. In absolute glaucoma, this procedure most often helps avoid enucleation. A detailed description of the authors' technique is given. An electrode is applied directly to the eyeball seven millimeters from the limbus, without dissecting the conjunctiva.

CRYSTALLINE LENS

Arruga, H. A method to extract secondary cataracts. *Ophthalmologica*, 1945, v. 110, Sept.-Oct., p. 224.

In order to extract a secondary membrane in toto a capsule forceps is introduced into the anterior chamber through an incision in the limbus. The forceps is pushed down behind the iris if the pupil is not well dilated. Pressure is applied with the fixation forceps which forces the secondary membrane into the capsule forceps. These are then closed, the membrane is loosened by zigzag movements as in intracapsular extractions and easily extracted. (1 photograph.)

F. Nelson.

Arruga, H. The corneal section and sutures in cataract extraction. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, April, pp. 331-338.

Arruga stresses the importance of hypotension and avoidance of pressure with the fixation forceps in making a good corneal section. He is sure that a corneal section need not be made rapidly. He makes the section in the limbus, stops bleeding points with the point of a heated strabismus hook, and introduces three to five sutures through the cornea, sclera and conjunctiva. (Illustration.)

Ray K. Daily.

Atkinson, W. S. Preliminary report of corneal section with long bevel and conjunctival flap for cataract extraction. *Trans. Amer. Ophth. Soc.*, 1945, v. 43, pp. 97-114.

The author points out the influence of the corneal section on operative and postoperative complications in cataract surgery. In order to prevent a leaky wound with shallow or empty anterior chamber and to decrease the occurrence of postoperative hemorrhage into the anterior chamber he suggests a section with a long bevel, and one placed in avascular corneal tissue. He favors the use of a keratome directed away from the iris and toward the apex of the cornea so that the length of the bevel is increased. Such an incision tends to close more firmly and tightly when the normal intraocular pressure is restored or the intraocular pressure is increased, but he points out that with the long bevel placed forward in the cornea it is essential to tumble the lens. This type of corneal section with conjunctival flap made with keratome and scissors is safe and with it the number of postoperative leaky wounds is reduced. Although hyphema

still occurs, the hemorrhages are smaller and less frequent.

François, J. **The complications of intracapsular cataract extraction.** *Ann. d'Ocul.*, 1946, v. 179, May, pp. 280-295.

An analysis of 415 cataract operations performed during nine years is reported. Intracapsular extraction was attempted in 87 percent of the patients. In 11 percent the capsule was prematurely opened. The principal complications were: vitreous loss, 7.1 percent; striped keratitis, 8.3 percent; hyphaema, 7 percent; vitreous opacities, 5 percent; iridocyclitis, 4 percent; glaucoma, 3.6 percent; retinal detachment and iris prolapse, 3.3 percent; choroidal detachment, 0.6 percent; and wound infection, 0.3 percent. Among the less severe complications encountered were striped keratitis, hyphaema, and choroidal detachment. Those of moderate severity included vitreous loss and opacities, and iridocyclitis. The severe complications were glaucoma, retinal detachment and wound infection. The operative procedure is described in detail.

Chas. A. Bahn.

Gát, L., and Orbán, L. **Acute psychoses after cataract operation.** *Ophthalmologica*, 1946, v. 112, Dec., pp. 335-343.

Two cases of acute psychosis after cataract operation are analyzed from the psychiatric standpoint. The first patient, 24 hours after an uncomplicated bilateral cataract extraction, suddenly became disoriented and violent with very specific hallucinations relating to a fire in which his barn and all his fine cattle were being destroyed without anybody helping him extinguish the fire. At the top of his voice he gave a vivid and most detailed de-

scription of his visual and acoustic hallucinations. He did not comprehend reminders that he had been operated upon, that he was in the hospital, or that he had to be quiet. Under bromides plus paraldehyde he quieted down and recovered within 24 hours, with a complete amnesia regarding the psychosis. When questioned about a fire on his property, he refused to answer. From his wife the information was obtained that one week before the operation his barn had burned down, that he had taken an active part in extinguishing the fire and had, at the time, felt badly about the animals that had been destroyed, but had not mentioned the incident again until the outbreak of the psychosis. In the opinion of the psychiatrist, this suppression of a shocking incident may have made it impossible for the patient to adjust himself to it. Thus a complex developed in his subconscious. Such complexes play an important role in the development of reactive psychoses.

The other patient also became acutely disoriented 24 hours after the operation; the main theme of his "argument" was that he should be permitted to do his work instead of being restrained for which there was no reason. Within 24 hours he recovered, but on psychiatric examination proved to be depressed and worried about his ability to earn a living. Further investigation revealed that he had reason to worry about his financial future. His earning power had been greatly reduced by his diminishing eyesight and a former wife had cheated him out of a piece of property which he wanted to will to his present wife to whom he was deeply attached and grateful. Thus, the main mechanism of these two acute psychoses was a pathologic reaction to actual experiences to which the patient

had not had an opportunity of adjusting himself. Precipitating factors are the strange surroundings and the exclusion of the visual corrective orientation. Peter C. Kronfeld.

García Ochoa, R., and Etschemendigaray, A. Post-tetany cataract. *Anales Argentinos de Oft.*, 1946, v. 7, Jan.-Feb.-March, pp. 7-9.

In a 41-year-old woman who had hyperthyroidism for a long time a thyroidectomy of the right lower lobe was performed finally, without complications. On the third postoperative day, acute tetany manifested itself for which calcium was given intravenously. The attacks persisted and required three separate graftings of parathyroid tissue on each side of the trachea. Thirteen months after the first appearance of tetany total cataracts developed in each eye. These cataracts, the authors feel, were definitely associated with the tetany of hypoparathyroidism. For prophylaxis they suggest the use of high doses of calcium, perorally and intravenously, and parathyroid tissue grafts. Edward Saskin.

Koke, M. P. Ciliary dilation and vitreous recession in cataract extraction. *Amer. Jour. Ophth.*, 1947, v. 30, March, p. 327. (References.)

Saint-Martin, R. Errors in cataract practice. *Ann. d'Ocul.*, 1946, v. 179, April, pp. 232-236.

Reduced ophthalmoscopic illumination and a narrow beam facilitate the examination of lens details. Concurrent glaucoma, diabetic and other systemic diseases of the choroid and retina that increase the risk of operation often are not recognized. Generally speaking, when vision is less than 20/50 in the better eye operation should be done

upon the other, unless uveitis from lens hypermaturity has made operation necessary sooner. General diseases which may affect the risks of the operation should be routinely searched for. Infections involving the lids or sinuses may decide the success or failure of cataract operation. Cataracts secondary to uveitis are more easily removed by intracapsular extraction, which, however, is not infrequently followed by atrophy of the eyeball. Undue pressure on the iris and ciliary body is a frequent cause of delayed healing. Akinesia, retrobulbar anesthesia, and paralysis of the superior rectus are essential. Where orbital hemorrhage follows injection, operation is best postponed. Sufficient corneoscleral sutures to keep the wound sealed are advised. Sulfonamides and penicillin are used locally in conjunctival infections. Although premature handling of the eye may cause damage, the surgeon should be thoroughly familiar with the course and progress by the sixth day.

Chas. A. Bahn.

Samuels, Bernard. Cataract in intraocular tumors. *Trans. Amer. Ophth. Soc.*, 1945, v. 43, pp. 331-343.

The author presents the microscopic findings of cataract formation in 57 globes, each containing an intraocular tumor. In 34 globes the tumor was a malignant melanoma, in 21 a retinoblastoma, in one an epithelioma of the ciliary body, and in another a sarcoma that invaded the ciliary body. He stresses the fact that the tumor was not in every instance the actual sole cause of the cataract, but often the result of complications that develop in the globe during the growth of the tumor or during its degenerative changes. Of the 57 tumors 26 were in contact with the lens. Seventeen of the melanomas were

necrotic, 12 almost entirely so, and all of the retinoblastomas showed signs of necrosis. Excellent microscopic enlargements of the sectioned globe reveal various pathological details such as: folds in the capsule, proliferation of the subcapsular epithelium, necrosis of the subcapsular epithelium, changes in the lenticular substance, calcification of the lens substance, cystic spaces, and vesicular cell formation. He feels that whenever there is a combination of cataract and glaucoma, and there is the slightest possibility of intraocular tumor, it is advisable to recommend the removal of the globe. He emphasizes the importance of the differentiation in childhood between retinoblastoma and metastatic ophthalmitis. A special cause for diagnostic error in tumors concealed by cataract is failure to obtain a complete history. The earliest sign of disturbance in vision may be a distortion of objects, or an impression of dark waves before the eye, or a sensitiveness to light in a certain quadrant, or even dizziness.

RETINA AND VITREOUS

Bertotto, E. V., and Abrebanel, V. **Persistent hyaloid artery.** *Anales Argentinos de Oft.*, 1946, v. 7, Apr-May-June, pp. 48-50.

Two cases of unilateral persistent hyaloid artery are presented. The first patient had a vision of 6/12 in the affected eye, which was also the seat of an old extramacular choroiditis. The second had, in addition to the hyaloid artery, a divergent strabismus, and a central scotoma due to macular choroiditis. (1 illustration.)

Edward Saskin.

Cojazzi, L., and Grandi, G. **Relations between retinal arterial pressure and vestibular stimulation.** *Riv. Oto-Neuro-Oft.*, 1946, v. 21, March-Apr., pp. 85-97.

Researches were undertaken to distinguish in the mechanism of vestibular vegetative manifestations the factors of vestibular stimulation from the extravestibular factors. There was an increase in retinal arterial pressure during vestibular stimulation with heat (Veit's method), during simple backward flexion of the head without direct labyrinthine stimulation, and in rotary stimulation (Barany's method). In rotatory stimulation (Buys-Fisher) in which extravestibular stimulation was excluded the retinal arterial pressure was not modified. This shows that the ampullar stimulation cannot be the origin of retinal vascular phenomenon. The latter appear with other vegetative phenomena when stimulations of extravestibular origin occur. (Bibliography.)

Melchior Lombardo.

Falcone, G. **Cyst in the vitreous and posterior cataract in retinitis pigmentosa.** *Indian Med. Gazette*, 1946, v. 81, Oct., pp. 417-418.

The author presents a case of primary pigmentary degeneration of the retina associated with posterior polar cataract in both eyes and a freely floating cyst in the vitreous of one of the eyes. The cysts have been found to be developmental anomalies of the hyaloid system and in some they seemed to result from intrauterine fetal disease. The posterior polar cataract and the cyst in this patient were considered to be due to embryonal changes in the hyaloid circulation and not to vitreous changes arising from the retinochoroidal disease.

Francis M. Crage.

Hruby, K. Recent clinical and pathological findings in examinations of the vitreous. *Wien. Klin. Wchnschr.*, 1946, v. 58, Aug., pp. 461-464.

The posterior parts of the vitreous can be examined with the slitlamp by aid of the contact glass or of an interposed lens developed by the author. This method of examination gives us a more thorough understanding of vitreous pathology. Posterior detachment of the vitreous is a frequent occurrence and is found in axial myopia, in senility, in tapetoretinal degenerations, after contusions and perforations, and in retinal detachment. Clinically, so called "formed" vitreous opacities are a certain sign of posterior vitreous detachment. A total posterior detachment of the vitreous is the most frequent type found in younger individuals who retain the normal vitreous structure, whereas in myopic and senile individuals there usually is a destroyed structure that leads to vitreous collapse. In others there is only a partial posterior detachment and this detachment may occur near the optic disc or above or below. There is no doubt about the existence of a posterior limiting membrane of the vitreous. This assertion is based on the clinical findings, because many pathologic changes formerly thought to be within the vitreous are actually between this limiting membrane and the retina. Formed vitreous opacities, the proliferations of retinitis proliferans, and intraocular cysticercus are examples of this kind. Some perforating foreign bodies do not intrude into the vitreous, but lead only to its indentation and rest between the limiting membrane and the retina. Detachment of the vitreous itself scarcely influences the function of the eye, but in certain cases it is the

main contributing factor for retinal detachment. The rapid shifting of the vitreous mass during movements of the eyeball may lead to flaplike tears. This may even happen in cases of partial vitreous detachment. Posterior detachment of the vitreous is always found in cases of primary retinal detachment. It is usually absent in cases of secondary detachment of the retina due to tumors and retinal cysts.

Max Hirschfelder.

Koch, F. Ophthalmoscopic differentiation of arteriolar sclerosis: hypertensive and atheromatous. *Geriatrics*, 1946, v. 1, Nov.-Dec., pp. 438-441.

The most useful classification, from the ophthalmoscopic as well as the systemic clinical point of view, is that proposed by Wagener and Keith. These authors employ a numerical grading system of 1 to 4 describing the intensity and degree of deviations from normal with regard to smooth attenuation of arteriolar caliber, focal or superimposed localized arteriolar constrictions (so-called nicking), arteriolar sclerosis, and presence of exudates and hemorrhages. These numerical gradings correspond to the adjectives mild, moderate, marked and severe. The gradings thus applied aid appreciably in determining the prognosis within each group, and are designated as I, II, III, and IV.

Ophthalmoscopically, patients classified as Group I exhibit smooth and uniform attenuation of arteriolar caliber, with little if any arteriolar sclerosis. Those in Group II uniformly reveal some degree of arteriolar sclerosis, together with narrowing or attenuation of caliber, but also may exhibit focal constrictions. Varying degrees of narrowing and sclerosis will be present in Group III, in association with cotton

wool exudates and hypertensive hemorrhages of varying types. In Group IV papilledema will have been added to all the findings observed in the preceding groups.

This classification permits the concept that, while all patients do not run the entire gamut from Group I to Group IV to exitus, the patient may experience relapses or remissions that will permit reclassification with regard to prognosis and life expectancy as well as changes in treatment from time to time.

Theodore M. Shapira.

Manlove, F. **Retinal and choroidal arterioles in malignant hypertension: a clinical and pathologic study of 15 cases.** *Arch. Inter. Med.*, 1946, v. 78, Oct., pp. 419-440.

The wall to lumen ratios of the retinal and choroidal arterioles measured in this series are greater than those of the arterioles measured in any other organ studied by this method except the lung. This is in accord with the work of Coats, who stated that the walls of arterioles observed in the eye are thinner than those in any other organ.

The wall to lumen ratios of arterioles are definitely decreased in malignant hypertension.

The most common manifestations of arteriolar lesions seen were medial hypertrophy and intimal proliferation. The choroidal vessels were much more affected than the retinal. Hyalinization of part or all of the arteriolar wall was seen frequently. Acute necrosis was seen occasionally.

No relationship was demonstrated between the arteriolar disease and other retinal lesions.

Theodore M. Shapira.

Reca, A. B. **Unusual posthemorrhagic hole of the macula.** *Anales Argentinos de Oft.*, 1946, v. 7, Jan.-Feb.-March, pp. 10-13.

A woman, 29 years of age, with hypertension and hypertensive changes in the retinal vessels, had a sudden and spontaneous loss of vision in the left eye. Examination revealed a fresh, almost spherical macular hemorrhage. In a little over three weeks the hemorrhage had become absorbed and in its stead was a horizontally oval hole in the macula. There was no papillary change. This condition must be differentiated from a post-traumatic macular pseudocyst which is usually surrounded by pigment. (2 illustrations.)

Edward Saskin.

Redslob, E. **The value of the venous retinal pressure.** *Ann. d'Ocul.*, 1946, v. 179, July, pp. 367-374.

The venous retinal pressure is minimal in diastole and maximal in presystole. The retinal capillaries form a barrier between the arterial and venous pressure mechanisms. In arterial hypertension and hypotension, the retinal venous pressure is not affected. A spontaneous venous pulsation was observed in 75 percent of 180 persons examined ophthalmoscopically by the author. The average retinal venous pressure is slightly less than 24 mm. Hg. The maximal pressure varied from 20 to 35 mm. Hg and the minimal from 9 to 15 mm. Hg. Both venous and arterial pressures can be measured by the Bail-lart dynamometer or less accurately by pressure on the sclera through the upper lid simultaneously viewing the retinal vessels with the ophthalmoscope. Retinal venous pressure varies with intracranial pressure because the

cerebrospinal fluid in the intervaginal space is in contact with the central retinal vein. Five illustrative cases are presented. These include cases of arterial hypertension, and increased intracranial pressure associated with a brain tumor, arachnoiditis, meningitis, and unilateral exophthalmos. (17 references.)
Chas. A. Bahn.

Redslob, E. Quinine intoxication. *Ann. d'Ocul.*, 1946, v. 179, April, pp. 218-220.

A 31-year-old woman during the second month of pregnancy used three grams of quinine internally as an abortifacient. Six hours later a bloody mass was expelled from the uterus, but blindness and deafness occurred at the same time. The next day, the discs were pale, the arteries small and the veins normal. There was strong mydriasis and practically no light reaction. The following day a stellar infiltration about the macula was observed in both eyes and fingers could be counted at two feet. Small doses of iodides were administered. Four days later the patient had entirely recovered from ocular symptoms which were believed due to retinal vascular spasm. Among the drugs which also produce simultaneous sight loss and deafness are: male fern, pelleterin, santonin, chenopodium, apiol, aniline, and salicylic acid.

Chas. A. Bahn.

Rosenblum, M. E. The basic principles of surgery of retinal detachment. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 10-12.

Of 1000 retinal detachment operations, by diathermy coagulation performed at the Helmholtz Institute, 54 percent were satisfactory. The first operations for detachment with a macular

hole were done by diathermy coagulation, with an orbitotomy to afford access to the macula. At present the operation is performed without an orbitotomy. A temporary tenotomy of the external rectus is done instead.

Ray K. Daily.

Rubino, A. Tentative surgical treatment of Coats's disease. *Riv. di Oft.*, 1946, v. 1, May, pp. 285-291.

In three eyes of two patients, diathermy coagulation of the choroid was performed. By transillumination, the area to be treated was outlined on the sclera; mild, prolonged, and deep application of the diathermy current is recommended, transscleral first, and perforating at the end of the operation to allow for escape of the subretinal fluid. Visual field diagrams show some improvement in one of the eyes; slight increase of visual acuity was observed in all of the eyes. The greatest improvement was from perception of hand movements to 2/50. Pigment formation was observed in the treated areas, and for four months, the pathologic process did not progress.

K. W. Ascher.

Vidal, Flaminio, and Damel, C. S. Retinal angiosclerosis and the neuroarteriolar test. *Arch. de Oft. de Buenos Aires*, 1946, v. 21, Jan.-March, p. 51.

The authors present the results of the neuroarteriolar test in retinal angiosclerosis. Variation of the intraocular pressure after stimulation of the arteriolar system of the eye with a sympathomimetic drug, such as ephedrine sulphate is observed. In 40 cases of retinal angiosclerosis the test was positive in 12 percent, negative in 75 percent, and inverse in 11.54 percent. The interesting feature in this study is the high percentage of inverse tests in an-

gioslerosis as compared with its absence in normal tension and physiologic hypotension. Plinio Montalván.

OPTIC NERVE AND TOXIC
AMBLYOPIAS

Carroll, F. D. Nutritional retrobulbar neuritis. *Amer. Jour. Ophth.*, 1947, v. 30, Feb., pp. 172-176. (3 figures, references.)

Fetterman, J. L., and Barr, J. H. Progressive syphilitic optic atrophy benefited by combined penicillin and fever therapy. Report of a case. *Arch. Derm. and Syph.*, 1946, v. 54, pp. 566-568.

The authors report a case of luetic optic atrophy with total blindness in one eye and progressive diminution in vision in the other eye. There was pallor of the disc in the better eye. The other disc was white. The Wassermann reaction of the spinal fluid was positive. Neurologic examination was negative.

Combined typhoid-malaria fever and penicillin therapy improved the vision in the better eye to almost normal. The blind eye remained unchanged. The patient returned to his work but suffered a recurrence 18 months later. Treatment has been resumed.

Francis M. Crage.

Fridman, S. J. Some characteristics of ocular involvement in craniostenosis. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 38-42.

Three patients had a history of headache and vomiting of many years duration, a fundus picture of old secondary optic atrophy, good visual acuity, and moderate constriction of the visual

fields. Roentgenoscopy revealed the presence of a moderate degree of craniostenosis. Ray K. Daily.

Hambreson, L., and Schepens, C. Tobacco amblyopia. *Ann. d'Ocul.*, 1946, v. 179, April, pp. 191-217.

The more or less excessive use of alcohol is considered of no practical importance in the development or severity of tobacco amblyopia. The hypersensitiveness of specific parts of the eye and eye brain to the several components of tobacco varies widely in different persons and depends on both genetic and environmental factors. Thus blindness has followed blowing tobacco smoke into an aching tooth cavity, and washing an itching skin with a tobacco lotion. Because of the inferior quality of tobacco and its defective fermentation during the war, tobacco amblyopia increased in France about 1000 percent.

The first symptom of tobacco amblyopia is usually a difficulty in recognizing colors, especially red. Vision is abnormally diminished in very bright light. These symptoms are usually binocular but not equally so. In monocular visual tests the patient more easily recognizes the letter to the nasal side, than the letter actually fixated. The initial lesion is a horizontal cocentral scotoma and is not pericentral. The peripheral field is usually normal, although occasionally a slight upper temporal constriction is observed. The relative increase of red over blue in scotomas is considered unimportant.

In 47 percent of a large series (the number is not mentioned) pallor and blurring of the temporal disc margin were observed. One third of the patients were less than 55 years of age, 47 percent were between 45 and 55

years, and 20 percent were more than 65 years of age.

Tobacco amblyopia must be considered part of a general intoxication which affects especially the autonomic nervous and cardiovascular systems. Tobacco is basically a vasoconstrictor, a hypertensor, a cardiac accelerator, and a miotic. The constitutional symptoms were greater, and recovery was less rapid in younger patients. Debilitating diseases, diabetes, syphilis, and some infectious diseases predisposed some individuals to tobacco amblyopia. Nicotine is detoxified in the liver where it is oxidized by glycogenic substances and produces a conjugate glucuronic acid. The basic pathologic lesion is a degeneration of the ganglion cells of the retina and atrophy of nerve fibers following a primary injury of the cones in the papulomacular area. The toxic substances reach the macular region through the retinal and choroidal capillaries which also degenerate. Production and action of the lipoid substance that is akin to vitamin A are interfered with, therefore red perception is reduced.

Complete abstinence from tobacco and maintenance of maximal nutritional activity are essential. The use of pilocarpine is of secondary value. (11 figures, references.)

Chas. A. Bahn.

Levatin, Paul. **Atrophy of the optic nerve following hemorrhage.** *Arch. of Ophth.*, 1947, v. 37, Jan., pp. 18-24.

After briefly reviewing the literature and discussing the theories, the author reports a case. Partial atrophy of the optic nerve developed in one eye in a 34-year-old white man during a massive hemorrhage from a duodenal ulcer and later in the other eye. Re-

peated determinations of the blood count and the blood pressure during this illness revealed a persistent state of peripheral circulatory failure and such an extreme acute anemia that ischemia is considered the chief etiologic factor in the production of the pathologic changes observed. The ophthalmologic findings suggest that ischemia can cause atrophy of the optic nerve either by producing degeneration of the retinal ganglion cells or by direct destruction of the optic nerve fibers in the region of the lamina cribosa. The former mechanism best explains the slow, delayed onset of partial atrophy of the right optic nerve in this patient, whereas the latter mechanism best explains the rapid, early onset of almost total optic atrophy of the left optic nerve.

R. W. Danielson.

Magnus, J. A. **Bilateral partial coloboma of the optic nerve.** *Brit. Jour. Ophth.*, 1946, v. 30, Nov., pp. 692-696.

Bilateral disc anomalies were seen in a 19-year-old boy. Both discs had rather marked nasal cupping. The tension was normal in each eye and remained so during provocative tests for glaucoma. Field defects exactly corresponded to the defects of the discs. A diagnosis of congenital coloboma of the nerves was made and glaucoma and cavernous atrophy were ruled out. (3 figures.)

Morris Kaplan.

Marthinsen, Reidar. **The supraclinoïd carotid aneurysm.** *Acta Ophth.*, 1941, v. 19, pt. 2, pp. 141-146.

A case of a large median supraclinoid aneurysm diagnosed clinically, and verified at operation is reported. The early ocular symptoms consisted of markedly reduced visual acuity, con-

centric contraction of the visual field with a central scotoma, and loss of color vision in the right eye. A year later there was loss of vision and central scotoma in the left eye. Four years later there was still further deterioration of vision, and atrophy of the left optic nerve.

Ray K. Daily.

Ravasini, Carlo. **An atypical case of Foster-Kennedy syndrome.** *Riv. Oto-Neuro-Oft.*, 1942, v. 19, March-April, pp. 133-152.

A 60-year-old male patient had migraine-like headaches on his right side for about three years and gradual loss of vision. While the headaches became less marked, the vision of his right eye was soon nil, and that of his left eye 3/10 with increasing constriction of the temporal field of vision. The right disc showed complete atrophy with sharp borders and normal retinal vessels, the left disc was slightly edematous, pale on the temporal side, and of almost normal color on the nasal. Later, the left disc showed a postneuritic atrophy. A meningioma of the right olfactory groove or of the smaller sphenoid wing was diagnosed. (3 X-ray photographs, 2 visual fields.)

K. W. Ascher.

Regoli, Attilio. **Meningioma of alveolar type, originating from the sheaths of the orbital part of the optic nerve.** *Riv. Oto-Neuro-Oft.*, 1942, v. 19, May-June, pp. 174-193.

A woman, 42 years of age, noted watering of her left eye. Three years later there was slight protrusion of her left eyeball, lid edema, and a reduction of vision of her left eye to 5/10 without a central scotoma. There was no pain or muscular paresis and X-ray films failed to show pathologic changes in the orbit during the first year after visual loss was noted; later there was

a slight shadow in the left orbit. Seven years later, when the exophthalmos reached 12 mm., and the optic disc was pale and its borders hazy the left orbit had a definite shadow in the X-ray picture. A hard, nonfluctuating mass was felt through the upper lid, and was removed under local anesthesia. The tumor was adherent to the posterior part of the optic nerve, measured 4 by 2.5 cm., and proved, on histologic examination, to be an extradural meningioma of alveolar type. Discussion of the differential diagnosis, pathogenesis, and literature follows; 73 meningiomas of the optic nerve were found in the literature among 399 cases of optic nerve tumor. (4 photomicrographs.)

Rønne, Henning. **The cytoplasmic inheritance in Leber's disease.** *Acta Ophth.*, 1945, v. 23, pt. 1, pp. 89-93.

The author replies to Lundsgaard's comment on his criticism of her theory of the inheritance of Leber's disease. He finds support for his contention that the disease is transmitted through the cytoplasm of the ovum in an analysis of Lundsgaard's familial series, which shows that 93 percent (plus or minus 5 percent) of the females are carriers of the disease. This does not disagree with twice the standard deviation from the 100 percent inheritance which one would expect. He attributes the absence of inheritance through affected males to the infinitesimal quantity of cytoplasm in the spermatozoa. (1 table.)

Wagener, H. P., Smith, H. L., and Nickeson, R. W. **Retrobulbar neuritis and complete heart block caused by digitalis poisoning.** *Arch. of Ophth.*, 1946, v. 36, Oct., pp. 478-483.

Chromatopsia, frosted or snowy vision, and flickering sensations have repeatedly been described in digitalis poisoning. Retrobulbar neuritis has not previously been reported. The authors observed a man, 50 years of age, with a complete heart block as the result of digitalis intoxication. Corrected vision was 6/60 in each eye and yellow vision was noted. The fundi were normal. The field of each eye contained an 8-degree relative central scotoma. Blue was not recognized in any part of either field. The physiologic blindspots were slightly larger than normal. The vision returned to normal in about five weeks without treatment except for the withdrawal of digitalis and an increase in the amount of fluid ingested by mouth.

VISUAL TRACTS AND CENTERS

Bender, M. B., and Teuber, H. L. **Ring scotoma and tubular fields; their significance in cases of head injury.** *Arch. Neurol. and Psychiat.*, 1946, v. 56, Sept., pp. 300-326.

In the literature, ring scotoma and tubular fields have been attributed to retinitis pigmentosa, luetic chorioretinitis, myopia, glaucoma, optic neuritis, commotio retinae, migraine, nasal sinusitis, hysteria, solar retinitis, and head injuries. Many authors consider these visual defects psychogenic, even

in head injuries, if the retina is normal.

The author describes a patient with head injuries, in whom extensive studies were made. He concludes that scotomas, despite their variability, have an organic basis. F. M. Crage.

Klachko, M. L. **Neuroophthalmic syndromes in fire-arm injuries of the occipital region.** *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 62-66.

The material for this analysis comprises 117 injuries to the occipital region. Fifty-two percent had hemianopsia, 11 percent concentric and other field defects, and in 36 percent the visual fields were normal. An analysis of the material and illustrative case reports lead Klachko to conclude that visual field defects and visual disturbances afford valuable diagnostic data in occipital injuries and localizing guides for the surgeon. Cortical blindness in occipital injuries is only infrequently permanent. When it lasts longer than a month it indicates an anatomic lesion in the visual centres. In injuries on a level of the external occipital protuberance hemianopsia is frequent. Heteronymous hemianopsia occurs in injuries in the midline of the occipital region. Homonymous hemianopsia is usually encountered in injuries to the lateral portion of the occipital region. Ray K. Daily.

Damel, C. S., Marino, Héctor, and Esperne, Pedro. Intraorbital dermoid cyst. Arch. de Oft. de Buenos Aires, 1946, v. 21, Jan.-March, p. 24.

A case of intraorbital dermoid cyst in a 7-year-old girl is reported. The cyst was located in the floor of the orbit and communicated with the skin of the lower lid through a fistulous tract that followed incision of the mass when it was mistaken for an abscess. There was cicatricial ectropion of the lower lid. The cyst and fistulous tract were excised and the ectropion corrected later by means of a skin graft. A brief discussion of dermoid cyst of the orbit is presented. (Bibliography.)

Dobyns, B. Exophthalmos and tissue changes in the guinea pig following administration of the thyroid stimulating hormone of the pituitary gland. West.

J. Surg., Obst., and Gynec., 1946, v. 54, Nov., pp. 411-427.

Following injections of the thyroid stimulating hormone (TSH), of the anterior lobe of the pituitary body, conspicuous exophthalmos occurs in guinea pigs regardless of the presence or absence of the thyroid gland or the testes. Concurrently a generalized connective tissue reaction occurs throughout the body and, at the same time, a profound change occurs in the body fat. Fat depots are rapidly depleted and replaced by edema and connective tissue. Polymorphonuclear leukocytes and macrophages participate in this reaction and appear to be phagocytizing fat. Macrophages appear to become fibroblasts which lay down connective tissue.

As further evidence of profound changes in fat following injection of TSH, great quantities of lipid appear in the liver, kidneys, muscles, and in some epithelium and reticuloendothelial cells. Values for plasma lipoids are elevated and polymorphonuclear cells of the blood stream seem to contain increased quantities of fat.

The data suggest that, as a result of administration of TSH in quantities sufficient to produce exophthalmos, there is a generalized alteration in metabolism of fat throughout the body and that a connective tissue reaction is associated with it. Thus, many of the changes in the orbital tissue which produce exophthalmos are expressions of generalized tissue changes.

EYELIDS AND LACRIMAL APPARATUS

Fox, S. A. **Some methods of lid repair and reconstruction. III. Socket reconstruction with epidermis.** *Amer. Jour. Ophth.*, 1947, v. 30, Feb., pp. 190-196. (8 figures, references.)

Gill, W. D. **Dacryocystorhinostomy.** *Amer. Jour. Ophth.*, 1947, v. 30, Feb., pp. 198-200.

Khurgina, E. A. **Blepharoplasty in war injuries.** *Vestnik Oft.*, 1946, v. 25, pt. 3, pp. 31-33.

The results of 196 plastic operations on the lids after war injuries are analyzed. Free transplants were used in 89 cases, grafts with a broad pedicle in 44, grafts with a narrow pedicle in 23, and transposition of tissues in 42 cases. Transplantation of fat was used freely to fill defects, and in some cases both fat and skin were successfully grafted. Khurgina emphasizes the importance of excising all cicatricial tissue; by surrounding the graft with normal tissue the post-operative shrinking is reduced to a minimum.

Ray K. Daily.

Philips, Thygeson. **Etiology and treatment of blepharitis.** *Arch. of Ophth.*, 1946, v. 36, Oct., pp. 445-477.

Detailed etiologic and therapeutic studies were made on 350 cases of marginal blepharitis encountered in military personnel. Only three important etiologic types could be distin-

guished in this series, namely: blepharitis due to seborrheic dermatitis, to pathogenic staphylococci and to hemophilus duplex (Morax-Axenfeld diplobacillus). There was a high incidence of mixed seborrheic and staphylococcic blepharitis. The three main etiologic types had distinct clinical characteristics and in their pure forms could be differentiated on clinical grounds alone in all but a few cases in which the staphylococcus blepharitis simulated hemophilus duplex blepharitis. Microscopic examination of scrapings from the lid margins facilitated determination of the etiologic agent. The finding of budding yeast forms, believed to be *Pithrosporum ovale*, was considered a diagnostic sign of seborrheic blepharitis, although its etiologic role in seborrheic dermatitis is still unsettled. Routine biomicroscopic examination of the lid margin in cases of chronic conjunctivitis revealed a high incidence of mild or subclinical blepharitis, which was usually staphylococcic. It is suggested that most cases of chronic conjunctivitis have their origin in blepharitis.

Treatment was carried out with a wide variety of agents. Seborrheic blepharitis responded best to treatment that consisted of daily mechanical cleansing of the lid margins, frequent expression of the Meibomian glands, applications of 0.25 percent solution of silver nitrate to the conjunctiva and 1 percent silver nitrate to the lid margins twice weekly, applications twice daily of an ointment containing 1 percent salicylic acid and 1 percent yellow mercuric oxide to the lid margins, and treatment of associated seborrheic dermatitis of the scalp, brows, and external ears. Sulfathiazole and penicillin applied in ointment form were ineffective.

Staphylococcic blepharitis responded well to topical treatment with the following preparations, listed in order of efficacy; penicillin, sulfathiazole or sulfadiazine, and such mercurial preparations as ammoniated mercury ointment and a combination of 1 percent mercuric oxide and salicylic acid in a petrolatum base. Administration of staphylococcus toxoid proved to be an important supplementary procedure. Staphylococcic blepharitis complicated by inflammation in the Meibomian glands was much more resistant to therapy than uncomplicated blepharitis. Blepharitis due to *Hemophilus duplex* responded completely and rapidly to topical application of sulfathiazole ointment.

17

SYSTEMIC DISEASES AND PARASITES

Albeaux-Fernet, M., and Loublé, G. **Modern concept of the adiposogenital syndrome.** *Arch. d'Opht.*, 1946, v. 6, no. 3, pp. 257-272.

The authors describe in detail the symptomatology of this syndrome and note the importance of differentiating it from dystrophia adiposogenitalis, essentially an incomplete form of the syndrome in which there are neither radiologic nor ophthalmologic signs and in which the obesity is generalized and not segmentary as in the complete syndrome. They differentiate the syndrome sharply from hydrolipopexia, Cushing's disease, adrenogenital syndrome, and the obesities of castration and the menopause. They conclude that errors in differential diagnosis are unfortunately frequent.

The importance of radiologic and ophthalmologic examination in every patient whose condition suggests this syndrome is stressed. The radiologic examination in a typical case with a chromophobic adenoma of the pituitary gland shows changes in the sella turcica including overall enlargement which is exaggerated in the antero-posterior diameter with modifications in the clinoid processes. Bony changes are seen in the sphenoidal sinus even

earlier and more constantly. The sinus loses its normal quadrilateral shape to become triangular, the triangle's base anterior. The cases with tumors of Rathke's pouch are more easily diagnosed radiologically. In 75 percent of cases calcified nodules are seen in the tumors. These, combined with changes in the sella turcica, are highly diagnostic. Ventriculography also yields important information in cases in which other diagnostic methods are inconclusive.

The ophthalmologic examination with visual field studies is even more important than the radiologic examination. It is not only essential for diagnosis of the pituitary lesion but is the only reliable means of following the results of therapy. The characteristic eye finding is bitemporal hemianopsia but unilateral temporal field defects may occur and rarely a homonymous hemianopsia or unilateral amaurosis. Ordinarily vision is affected late as are the pupil and fundus.

The authors describe in some detail the various modifications of the syndrome and its relationship to the syndrome of Laurence-Bardet-Biedl. Etiologically they consider the pure syndrome to be due to a chromophobic adenoma or to a craniopharyngioma. With respect to treatment they discuss radiotherapy and neurosurgery and conclude that surgical intervention is now the treatment of choice to be resorted to when there are important ophthalmological changes such as bitemporal hemianopsia or signs of optic atrophy. Phillips Thygeson.

Costi, C., and Marñón, G. **Uveoparotid fever (Heerfordt's syndrome).** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Dec., pp. 1122-1129.

The authors report their observation

of Heerfordt's syndrome, characterized by bilateral uveitis, swelling of the parotid glands and low grade fever between 99 degrees and 100.5 degrees, in a woman, 49 years of age. There also was swelling of the submaxillary and lacrimal glands.

J. Wesley McKinney.

Esente, Ivan. **Photophobia with infantile acrodynia.** Riv. di Oftalm., 1946, v. 1, June, pp. 392-408.

Infantile acrodynia, also referred to as vegetative neurosis, erythroedema, trophodermatoneurosis, dermatopolynuritis, occurs not infrequently in northern Italy. The majority of cases described in the literature had, among other manifestations, a rather severe photophobia, which also was present in five patients observed by Esente. There was no pain, and only slight lacrimation and a mild blepharospasm. Only one of his patients complained of a coexisting headache, one had a very mild conjunctival hyperemia, and none showed any corneal or uveal disease, orbital or periorbital lesion, paresthesias, or vasomotor or trophic disturbances. The acroparesthetic symptoms and the complaints of pain always preceded the photophobia, which, however, itself preceded or accompanied the appearance of mental symptoms such as insomnia, asthenia, dysuria, and emaciation. With general improvement the photophobia disappeared earlier than the diencephalic disturbances. After an extensive discussion of the pathogenesis of acrodynia and of different types of photophobia, the author concludes that in acrodynia there most probably is an alteration of the retinal metabolism that is responsible for the retinal hyperexcitability. A psychosomatic mechanism, localized in

the diencephalon is profoundly altered by the disease process.

K. W. Ascher.

Esteban, Mario. **Ocular filaria.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Dec., pp. 1097-1112.

A European girl had lived for two years in Spanish Continental Guinea. Seven years after her return to Spain she began to complain of pricking sensation of her left lower lid and something moving beneath it. A small tumor mass, which changed its shape and position was found. When the patient was operated on in novocaine anesthesia an adult female *Filaria Loa* was found and removed. In the specimen of blood many microfilarias of *Filaria Loa* were found. (6 illustrations.)

J. Wesley McKinney.

Foss, Björn. **Is there a K avitaminosis in hemorrhages after intraocular operations?** Acta Opth., 1941, v. 19, pt. 1, pp. 15-24.

The prothrombin concentration of the blood, using Nygard's modification of Quick's method, was determined in 54 patients with cataract, glaucoma, retinal hemorrhage, thrombosis of the central retinal vein, right sided hemianopsia, iritis with hyphemia, and thrombopenia. In 12 of 48 patients there was immediate or delayed post-operative bleeding. An analysis of the prothrombin concentrations, does not indicate that a vitamin K deficiency was a factor in these hemorrhages. One patient with cataract and sprue was found to have a deficiency of prothrombin, and was given 20 mgm. of vitamin K intramuscularly before the operation; the operation was then performed without hemorrhage. (4 tables.)

Ray K. Daily.

García Miranda, A. **Ocular diabetes.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Dec., pp. 1041-1092.

The author reviews the different effects of the diabetic process in the eye, giving the greatest importance to the retina and the crystalline lens. Statistics do not agree as to the percentage of lesions in the eyes which probably result from other causes, mainly renal or vascular diseases. (4 illustrations.)

J. Wesley McKinney.

Gordon, D. M. **Ocular sporotrichosis.** Arch. of Ophth., 1947, v. 37, Jan., pp. 56-72.

Forty-eight cases of ocular sporotrichosis have been reported in the world literature, including the case reported in this paper. Apparently in 34 of these cases the ocular disease was primary and in 15 secondary to involvement elsewhere in the body.

The cases are distributed anatomically as follows: lids, 17; conjunctiva, 10; lacrimal sac, 2; conjunctiva and lacrimal apparatus, 1; brow, 1; intra-ocular, 5; orbit and lids, 5; cornea, 3; limbus, 1; uveal tract (without other lesions), 1, and lacrimal canal, 1.

Of the 48 reported cases, 10 have occurred in the United States and the majority of the remainder in France. (60 references.) R. W. Danielson.

Harrington, D. O. **Ocular manifestations of psychosomatic disorders.** Jour. Amer. Med. Assoc., 1947, v. 133, March 8, pp. 669-674.

Few ophthalmologists seem to be aware of the role played by emotion in the production of discharge from the autonomic nervous system and the profound vasomotor disturbance produced. Mental conflict and emotional disturbances such as tension, anxiety, embarrassment, irritation, fear, anger, rebel-

lion, inadequacy, insecurity, humiliation, grief, depression, despair, and excitement may be the causative factor in amauroses fugax, migraine neuro-circulatory asthenia, central angiospastic retinopathy, Raynaud's disease, glaucoma, and ocular hysteria in a susceptible individual.

Irwin E. Gaynon.

Koutseff, A. **Premenopausal oculo-palpebral syndrome.** Ann. d'Ocul., 1946, v. 179, July, pp. 389-398.

The complete syndrome consists of palpebral edema, ocular chemosis, vascular hypertension, ocular hypertension, concentric contraction of the fields, and transient myopia. Two cases are described. In the first patient these symptoms practically always became worse on the second day of menstruation. Following treatment with folliculine, a female sex hormone, the condition greatly improved. In the other patient, both eyes had been operated on for glaucoma; the ocular symptoms were similar to those in the first patient. The syndrome is similar to that observed in eclampsia and involves malfunction of the pituitary and adrenal glands.

Chas. A. Bahn.

Krause, A. C. **Congenital encephalo-ophthalmic dysplasia.** Arch. of Ophth., 1946, v. 36, Oct., pp. 387-444.

This is a detailed presentation of a clinical entity that has been described previously in part but not as a complete syndrome. The disease is characterized by retinal and cerebral hypoplasia and hyperplasia. The ocular changes may include microphthalmos, malformations of the retina, choroid, and optic nerve, retinal dysplasia, retinal glial membranes, cones and septums and persistent remains of the hyaloid artery. Other effects are ret-

inal atrophy, gliosis, fibrosis, intra-ocular hemorrhages and exudates, secondary glaucoma, atrophy of the iris, anterior and posterior synechias, cyclitic membranes, choroidal and scleral atrophy, and cataracts.

The cerebral dysplasia is shown by the heterotopias and the hyperplasia, hypoplasia, and aplasia of the cerebrum and cerebellum. The secondary effects are the hydrocephalus, arising from the cerebral and arachnoidal dysplasia, and the microcephaly resulting from the cerebral and cerebellar agenesis.

Eighteen cases of this syndrome are described. The disease was more commonly found in premature infants and in single infants of a multiple birth. The common neurologic signs were mental retardation, microcephalus, and hydrocephalus. In some cases the brain showed cerebral and cerebellar hyperplasia, hypoplasia and agenesis, heterotopias, and internal hydrocephalus. Clinically, the ocular disease rarely occurred without neurologic signs of involvement of the brain when the child was examined after the age of four years. The ocular signs were loss of vision, ptosis, enophthalmos, microphthalmos, strabismus, retinal detachment, postlental masses, retinal atrophy, gliosis, recurrent retinal and vitreous hemorrhages, anterior and posterior synechias, secondary glaucoma and cataract. No method of treatment was found to prevent or to cure the disease.

John C. Long.

Lauda, E. Findings and treatment in Reiter's syndrome. *Wien. Klin. Wchnschr.*, 1946, v. 58, pp. 55-56. (See Section 5, Conjunctiva.)

Leoz de la Fuente, G. Ocular pemphigus. *Arch de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Dec., pp. 1113-1121.

The author reports a case of ocular pemphigus in a man, sixty years of age who showed bilateral pseudoptosis, total retraction of the conjunctiva and complete disappearance of the cul-de-sac, and photophobia without lacrimation. The patient's corneas were clear. The man had five plaques of pemphigus on the mucosa of the nose. (5 illustrations.)

J. Wesley McKinney.

Maestro, Tullio. Polyradiculoneuritis with albumino-cytological dissociation (Guillain-Barre's syndrome) with involvement of ocular nerves. *Riv. Oto-Neuro-Oft.*, 1942, v. 19, May-June, pp. 153-173.

The author observed two cases of this syndrome. In one patient there was bilateral involvement of the third and sixth nerves, and unilateral facial nerve involvement; in the second patient, there was a bilateral involvement of the third and of the sixth nerve and a unilateral involvement of the fourth, the sensory portion of the fifth, and the cervical sympathetic nerve. The increase in albumin in the cerebrospinal fluid without increase of its cell content can be explained by absence of inflammation while congestion and edema are present. Therapy consisted in administration of antidiphtheria serum, artificial fever, autohemotherapy, B vitamin, salicylate of sodium, and repeated lumbar punctures. Prognosis is favorable. The first description of this syndrome was published by Guillain, Barre, and Strohl, in 1916.

K. W. Ascher.

Rubino, A. The uveal-meningitic syndrome. *Riv. Oto-Neuro-Oft.*, 1946, v. 21, March-April, pp. 73-84. (See Section 7, Uveal tract, sympathetic disease, and aqueous humor.)

Santoni, Armando. **Tuberculous bacillemia and its importance in tuberculous infections of the eye.** *Arch. di Ottal.*, 1946, v. 50, May-June, pp. 97-137.

Hemoculture according to the method of Lowenstein was carried out (often several times) in 15 patients with iridocyclitis, the tuberculous nature of which was either fairly certain or quite probable. All but one culture was negative. In four patients with iridocyclitis and in one with papiloretinitis which were almost certainly sympathetic, the cultures were negative. In two patients with tuberculosis of the conjunctiva and in one with tuberculoma of the epibulbar tissue and Pott's disease in whom the organism could be isolated from the conjunctiva, blood cultures were repeatedly negative. Cultures were also negative in one patient with sclerokeratitis associated with tuberculous arthritis of the knee, in two with retinal periphlebitis, and in several with recurrent vitreous hemorrhage, heterochromia of the iris (Fuchs type), and post-traumatic uveitis.

Although blood cultures are not a diagnostic aid and the diagnosis of tuberculous lesions of the eye must still be clinical, these results add emphasis to the theories of Lowenstein and Meller as to method of production of ocular lesions of tuberculous origin. It has been shown by Baumgarten and Weichselbaum that tubercle bacilli can be present in tissues for some time in an inactive state. It is possible that reactivation of their virulence can be brought on by the renewed presence of toxins or lowered resistance, in previously sensitized tissues. Negative cultures can also be explained on the basis of the work by Mazzetti and his collaborators who showed that the bacilli of artificially produced bacille-

mia disappeared in direct ratio to the resistance of the animal to the infection.

Francis P. Guida.

Talbot, H. **Ocular lesions in internees at a civilian internment camp at Hong Kong.** *Brit. Jour. Ophth.*, 1946, v. 30, Nov., pp. 688-692.

Of 278 internees who presented themselves to the camp clinic complaining of ocular symptoms, 82 percent had appreciable contraction of the visual field. This constriction often was quite severe. Many patients had a marked pallor of the disc, and chronic conjunctivitis was very common. They complained of headache, temporary loss of vision, flickering vision, night blindness, glare, and eye strain. These signs and symptoms were unmistakably due to malnutrition and were found to be irremediable.

Morris Kaplan.

Tassman, I. S. **Ocular changes in the blood dyscrasias.** *Arch. of Ophth.*, 1947, v. 37, Jan., pp. 42-55.

A resumé of the eye findings in these dyscrasias is given as well as case reports of erythrocytosis, pernicious anemia, and splenic anemia.

R. W. Danielson.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Chance, Burton. **Exposure and fixation of the eye in the early days of cataract extraction.** *Arch. of Ophth.*, 1946, v. 36, Oct., pp. 484-497.

This is an interesting paper on the early use of speculae and various fixation devices during cataract extraction. Numerous instruments are illustrated.

John C. Long.

James, R. R. **Ophthalmology in lectures of a century ago.** Brit. Jour. Ophth., 1946, v. 30, Nov., pp. 658-659.

A few ophthalmic extracts are given from a volume of lectures by Abernethy on anatomy, surgery and pathology which were published 115 years ago. Several references are made to ocular tumors and to couching of cataracts.

Morris Kaplan.

Kuhn, H. S. **Industrial ophthalmology.** Jour. Am. Med. Assoc., 1946, v. 132, Nov. 30, pp. 772-777.

The term "industrial ophthalmology" is considered obsolete, the more correct one is "occupational ophthalmology." Educational opportunities for ophthalmologists interested in this work are lacking at present but industry will demand the services of ophthalmologists.

Visual mass testing techniques are described. They are considered valuable in that important visual data such as distance and near acuity, with and without correction, distance and near phorias, distance and near stereopsis, and color appreciation are secured and recorded for each employee. The tests are not thought of as eye examinations but are placed in the category of aptitude examinations. The results guide the applicant to the proper job for him and lead others to the ophthalmologist for corrective care. The various instruments used are briefly described.

Relationship between management and the physician requires a definite understanding of what the employer can gain, as well as his responsibilities to his employees.

The author expresses an earnest desire that more ophthalmologists will become interested in occupational ophthalmology.

Francis M. Crage.

Luc, Jan. **Plastic restoration of upper lid and socket.** Brit. Jour. Ophth., 1946, v. 30, Nov., pp. 665-668.

On a shrunken socket a modified Esser's plastic repair was accomplished with good result. A skin graft from the arm was folded around a dental mold and sutured into the opened socket. It healed without contracture.

Morris Kaplan.

Rutherford, C. W. **Gerontology and the eye, with some remarks on old age.** J. Indiana St. Med. Assn., 1946, v. 39, May, pp. 209-212.

The ocular characteristics of old age arise from two related processes, namely, histologic alterations in the vascular tissues, and deficiency in the fat soluble vitamins. Degenerative senile processes in the cornea, iris, lens, vitreous, retina, choroid, optic nerve, eyelids, eye muscles are described.

Several suggestions for the alleviation of ocular symptoms in senile patients are made. A brief paragraph tells what the state of Indiana is doing to help the senile patient. It is the responsibility of physicians to treat the aged patient just as much as to treat the infant or the young adult.

John B. Hitz.

Ten Doesschate, G. **Some historical notes on spectacles and on beryllus.** Brit. Jour. Ophth., 1946, v. 30, Nov., pp. 660-664.

A short discussion is presented of the origin of spectacles and their association with beryllus with which term the word spectacles is associated in many foreign languages. Beryl is a precious stone family that includes the emerald and aquamarine and through which magnification might have first been noted. In addition the beryl was

supposed to have possessed some mystic curative power. Morris Kaplan.

Velter, Edmond. *Ophthalmology and neurology in France from 1939 to 1945*. Arch. Chilenos de Oft., 1946, v. 2, Jan.-Feb., pp. 7-10.

The article, which is in French, is preceded by a full-page portrait of the author.

Very briefly the writer mentions a considerable number of literary contributions to these general fields of medicine which were presented to different societies during the war period. He comments that "the conditions created by mobilization and the occupation caused a dispersion of the hospital personnel and that of the laboratories, to which dispersion was added the impossibility of obtaining apparatus, instruments, chemical products and dyes, laboratory animals and their food. Limitations as to gas and electricity rendered impossible the functioning of a great part of the apparatus, especially incubators; and lack of heating made the institutions uninhabitable during the long winter months."

W. H. Crisp.

19

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Druault, A., and Druault, S. *The eyes of the new born*. Ann. d'Ocul., 1946, v. 179, July, pp. 375-388.

At birth the diameter of the normal eye is 17 to 18 mm. The cornea is relatively large, 9 to 10 mm. in diameter. The choroid is relatively thick and the ciliary body is not well developed. The optic nerve fibers are myelinated. The lacrimal apparatus is not well developed and a diaphragm frequently exists in the sac at birth. Crying does not occur until about the sixth week of infant life. The growth of the orbit

depends upon the completeness of its contents; therefore enucleation in infancy prevents full development of the face. The weight of the eye at birth is about 2.29 grams which is one-third of that of the adult eye. At birth there is a fetal structure, the scleral protuberance of Von Ammon, which corresponds to the macula. During the eighth month of fetal life the cornea is opaque, but at birth it is entirely transparent. Descemet's membrane does not form until the sixth month after birth. At birth the sclera is bluish because it is thin and translucent. Because of the absence of epithelial pigment in the iris at birth, most children are born with blue eyes, though in some strongly pigmented races the iris may be a very dark brown. The crypts of the iris are not well formed until after the first year. The pupillary membrane of Wachendorf is absorbed during the eighth month of fetal life. Pupillary contractions occur during the fifth month of fetal life. Accurate vision is questionable until at the age of three months when the myelination of the optic nerve is complete. The pigmentation of the suprachoroid begins at birth and is not complete for one year. The number of rods and cones does not increase with the increasing development and size of the eye. No mitoses occur in the retina after the fourth month of fetal life. The papilla of the newborn is more deeply colored than in adult life, but has the same individual differences. The lens, at birth, has about one-half the adult thickness. The posterior star is more developed than the anterior and zonular fibers are apparently more numerous than in the adult. The hyaloid artery disappears before the ninth month of fetal life. The canal of Cloquet is a condensation of vitreous tissue around the hyaloid vessels.

PAN-AMERICAN NOTES

Edited by M. URIBE TRONCOSO, M.D.
500 West End Avenue, New York 24

Communications should reach the editor by the 12th of the month

III PAN-AMERICAN CONGRESS OF OPHTHALMOLOGY

The date of the meetings of this Congress has been advanced by the committee in Havana, Cuba, due to difficulties to obtain reservations in the hotels at a later date in the season. The meetings will be held from January 4 to 10, 1948. Arrangements are being made with travel agencies to offer transportation to Havana either by plane, or railroad and boats. To obtain reservations in hotels, members are advised to write as soon as possible to Dr. Tomas Yanes, P.O. Box 970, Havana, Cuba.

The agenda of the III Congress will be: (1) Presentation of official and of free scientific papers. (2) Sessions pertaining to research. (3) Scientific and commercial exhibits. (4) Courses of instruction. (5) Moving picture exhibits.

Official papers; that is, papers read in representation of an institution, should take not more than 20 minutes, including time for screen projections, and they should be accompanied by a summary of not more than 600 words.

Dr. Thomas D. Allen, 122 South Michigan Avenue, Chicago 3, Illinois, U.S.A., is in charge of the courses of instruction; and Dr. Gilberto Cepero, Calle L No. 353, Vedado, Habana, Cuba, of the moving picture exhibits.

Official papers should be mailed on or before August 23, 1947.

MEXICAN OPHTHALMOLOGICAL SOCIETY

This society, formerly combined with the Otolaryngological Association, has separated in two different branches. New elections were held for the board of the Ophthalmological Society, with the following results: president, Dr. F. Palomino Dena; secretary, Dr. Teofilo Agundis (Lucerna, 63, Mexico D.F.). Meetings will be held monthly. The society's journal will revert to its original name: *Anales de les Sociedad Mexicana de Oftalmologia*, and will be under an editor-in-chief, Dr. M. Puig Solanes, and a large committee on publication which includes many representative members. It will appear every two months.

ASSOCIATION FOR THE PREVENTION OF BLINDNESS IN MEXICO

This association will hold its third annual Scientific Week from August 11 to 16, 1947, in Mexico City. Contributions to the meeting from American ophthalmologists will be welcomed and should reach the secretary of the associa-

tion, Dr. Daniel Silva (Gomez Farias 19) not later than July 10, 1947. The papers should be original, not published before, and accompanied by a short abstract.

NATIONAL INSTITUTE OF OPHTHALMOLOGY IN MEXICO

An official decree of the President of the Republic has recently created a "Patronato" or board of trustees to be in charge of the building, equipment, and management of an "Instituto Nacional de Oftalmologia" which will be devoted to the treatment of patients with eye diseases, and to research work on ophthalmology and teaching, both for undergraduate and postgraduate students. The latter will be in connection with the National University of Mexico. Five members of the Patronato will be private, outstanding business and professional men and the sixth, ex officio member, will be the Secretary of Health and Public Welfare in the cabinet of the President.

The Federal Government has deeded to the trustees the necessary ground space for the construction of three units: an ophthalmological hospital of about 100 beds, an outdoor department and dispensary, and one building for research laboratories and teaching purposes. The trustees have already received the grounds and have started the foundations of the hospital. This is located near the magnificent Instituto Nacional de Cardiologia, recently opened and now in successful operation. The Institute of Ophthalmology will be of the same architectural style as the group of special hospitals near the General Hospital of Mexico City.

The trustees have already established several fellowships in ophthalmology for promising young Mexican physicians to study in this country and England for one year and then to become members of the medical staff of the Institute.

CHILEAN OPHTHALMOLOGICAL SOCIETY

This society has established a postgraduate course of ophthalmology which will last two years and of which at least one year will be devoted to internship in an ophthalmologic service. The basic subjects, anatomy, microscopic anatomy, embryology, physiology, pathology, bacteriology, and so forth, will be taught by members of the society under a director who shall be professor of the university. A certificate of attendance will be given to students taking the complete course.

V. BRAZILIAN CONGRESS OF OPHTHALMOLOGY

This congress met at the city of Salvador, Baia, from June 28, to July 2, 1946, and was presided over by the Secretary of Health and Education of Brazil. Three official subjects were presented: (1) Vision Requirements for Motor Drivers, by Dr. Pereira Gomes of Sao Paulo. (2) Abiopathic Diseases of the Macular Re-

gion, by Prof. Jorge Malbran and Prof. Carlos S. Damel of Buenos Aires. (3) Vitamins in Ophthalmology, by Dr. Joviano Rezende, Dr. Geraldo Queiroga, and Dr. Heitor Marback. (4) Glaucoma, by Dr. Renato de Toledo, Dr. Jacques Tupinamba, and Dr. Rui Rolim. Several surgical demonstrations were held at the hospitals.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. Ross Epting Anderson, Jackson, Mississippi, died January 15, 1947, aged 48 years.

Dr. George Freiman, Brooklyn, New York, died January 3, 1947, aged 53 years.

Dr. John Marvin Ingersoll, Miami, Florida, died January 16, 1947, aged 77 years.

Dr. Thomas Otis Klingner, Springfield, Missouri, died January 7, 1947, aged 72 years.

Dr. James Orville MacDonald, New York, New York, died January 13, 1947, aged 54 years.

Dr. Edward Rodgers Neep, Colorado Springs, Colorado, died November 21, 1946, aged 79 years.

Dr. Albert Ernest Rector, Appleton, Wisconsin, died January 13, 1947, aged 73 years.

MISCELLANEOUS

N.S.P.B. SCHOLARSHIPS

Nine one-year scholarships of \$1,000 each have been established by the National Society for the Prevention of Blindness for students who wish to qualify themselves for work in sight conservation and the prevention of blindness. Hospitals, public and private blindness-prevention agencies, and various organizations offering medical-care programs now have positions waiting to be filled. Applications for the scholarships, which are now open, may be obtained by writing the National Society for the Prevention of Blindness, 1790 Broadway, New York 19.

DELTA GAMMA SCHOLARSHIPS

Information on basic qualifications for the Delta Gamma scholarships for students interested in professional education in blindness prevention and sight conservation may be obtained from Mrs. Richard P. Miller, 39 West Jefferson Road, Pittsford, New York.

UNIVERSITY OF GLASGOW MEETINGS

During April, a series of meetings was held in the Department of Ophthalmology of the

University of Glasgow, Scotland. On April 9th, Prof. W. J. B. Riddell spoke on "American Gleanings." Dr. R. Leishman was the speaker for the April 16th meeting. His subject was "Chemical Injuries of the Cornea." "Industrial Cataract" was the subject presented by Dr. J. D. Fraser on April 23rd, and on April 30th, Dr. A. Mellick spoke on "Heterophoria."

SCHOLARSHIPS HONOR DR. CARY

At the celebration in honor of the 75th birthday of Dr. Edward Henry Cary of Dallas, Texas, the sum of \$20,000 for scholarships in his name was presented to Dr. Cary by Pres. Umphrey Lee of Southern Methodist University, Dallas.

LECTURES AT MANHATTAN HOSPITAL

During the first two weeks in April, Dr. Arthur Linksz concluded his series of lectures on "Physiological and Geometrical Optics," at the Manhattan Eye, Ear, and Throat Hospital, New York. On April 22nd, Dr. David H. Webster lectured on "Cataract Surgery." Dr. Guernsey Frey spoke on "Office Management and Routine," on April 24th. "Injuries of the Globe" was the subject of the lecture by Dr. Frank C. Keil on April 29th.

SOCIETIES

LOUISIANA-MISSISSIPPI MEETING

The Louisiana-Mississippi Ophthalmological and Otolaryngological Society held its annual meeting at the Buena Vista Hotel, Biloxi, Mississippi, on May 5th. Dr. Peter C. Kronfeld of Chicago spoke on "Newer Trends in the Treatment of Ocular Diseases." "Allergic Problems Seen by the Ophthalmologist and Otolaryngologist," was the subject of an address by Dr. Ralph Bowen, Houston, Texas. The J. Raymond Hume Memorial Address was given by Dr. Henry L. Williams of Rochester, Minnesota, whose subject was "Meniere's Disease." Dr. Samuel Fomon, New York, spoke on "The Rhinoplastic Operation and the Restoration of Nasal Function."

READING SOCIETY ATTENDS CLINICS

Temple University Hospital, Philadelphia, was the March 19th meeting place for the Eye, Ear, Nose, and Throat Society of Reading, Pennsylvania. Wet and dry clinics were conducted by Dr. Matthew S. Ersner.

SPEAKS AT MILWAUKEE MEETING

At the regular meeting of the Milwaukee Oto-Ophthalmic Society on March 25th, Dr. Derrick Vail, professor of ophthalmology, Northwestern University Medical School, Chicago, spoke on "Some Clinical Aspects of the Blood Supply of the Optic Nerve."

CLEVELAND GUEST SPEAKER

The guest speaker at the March dinner meeting of the Cleveland Ophthalmological Club was Dr. Thomas D. Allen, associate professor of ophthalmology at Rush Medical School, Chicago. The subject of his address was "The Value of a Complete Ophthalmological Examination."

PENNSYLVANIA ACADEMY MEETING

Dr. William L. Benedict of the Mayo Clinic, Rochester, Minnesota, was guest of honor at the annual meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology in Harrisburg on April 26th and 27th. "Tumors of the Orbit," and "Medical Societies and Medical Education," were the subjects of the two papers given by Dr. Benedict. Dr. Francis Heed Adler of Philadelphia, spoke on "Problems in the Diagnosis and Treatment of Chronic Simple Glaucoma," and Dr. Charles Kutscher of Pittsburgh, spoke on "Contusions of the Eyeball." Other speakers were: Dr. Thomas B. McCollough, Dr. Albert P. Seltzer, and Dr. LeRoy Polvogt.

CINCINNATI SOCIETY REVIVED

At its first meeting since November, 1928, the revived Cincinnati Ophthalmological Club had as guest speaker, on March 14th, Dr. A. D. Ruedemann of the Cleveland Clinic, who spoke on "Beta Radiation."

ANNOUNCEMENTS

OXFORD OPHTHALMOLOGICAL CONGRESS

On July 3, 4, and 5, 1947, the Oxford Ophthalmological Congress will convene at the Department of Human Anatomy, Oxford. The congress will open with a discussion on "The Contracted Socket," which will be led by Prof. T. Pomfret Kilner and Mr. H. B. Stallard. The Doyne Memorial Lecture will be delivered by Prof. L. S. Stone of Yale University, and will be entitled "Return of Vision and Functional Polarization in the Retinae of Transplanted Eyes."

EXAMINATIONS FOR TECHNICIANS

American Orthoptic Council examinations will be held in September and October, 1947. Written examinations will be given in various cities on Friday, September 12th. Only those passing the written examinations will be permitted to take the oral and practical tests to be given in Chicago, October 11th. Applications on official forms must be received before July 1, 1947. Address the American Orthoptic Council, 23 East 79th Street, New York 21.

WILDER MEMORIAL LECTURE

The third William Hamlin Wilder Memorial Lecture of the Institute of Medicine of Chicago will be delivered by Dr. John Q. Griffith, Jr., Laboratory for the Study of Hypertension, Philadelphia, on Friday evening, May 23rd, at the Palmer House. His subject will be, "Rutin: A Therapy for the Hemorrhagic Complications of Hypertension."

RESEARCH ASSOCIATION PROGRAM

The Association for Research in Ophthalmology, Inc., will convene at the Atlantic City Junior High School auditorium, Ohio and Pacific Avenues, Atlantic City, New Jersey, at 8:30 A.M. on Tuesday, June 10th. The program to be given follows:

Morning Session

(8:30 A.M. to 12 M.)

1. Bilateral Granulomatous Uveitis from the Use of Horse Serum in Rabbits.
T. F. Schlaegel, Jr., M.D., Department of Ophthalmology, Indiana University Medical Center, Indianapolis.
2. Stimulation of Corneal Epithelization with Local Application of Erythrocytes.
Frank W. Newell, M.D., Department of Ophthalmology, Northwestern University Medical School, Chicago.
3. The Effect of Di-isopropyl Fluorophosphate on the Capillaries of the Anterior Segment of the Eye.
Ludwig von Sallmann, M.D., College of Physicians and Surgeons, Columbia University, New York.
4. Transfer of Ascorbic Acid and Related Compounds Across the Blood-Aqueous Barrier.
V. Everett Kinsey, Ph.D., Howe Laboratory, Boston.
5. Acute Reversible Cataract in Chicken Due to Various Nitro-Compounds.
Wilhelm Buschke, M.D., Wilmer Ophthalmological Institute, Baltimore.
6. Virus Studies in Lymphomatoid Disease of the Ocular Adnexa.
Alson E. Braley, M.D., Assistant Professor of Ophthalmology, College of Physi-

cians and Surgeons, Columbia University, New York; Rose Alexander, M.S., College of Physicians and Surgeons, Columbia University, New York.

Executive Session

(1:15 P.M.)

7. Cyanide Inhibition of Corneal Respiration. W. A. Robbie, Ph.D., P. J. Leinfelder, M.D., T. D. Duane, M.D., University Hospitals, Iowa City, Iowa.
8. Ocular Effects of Tridione. Louise L. Sloan, Ph.D., Anita Peek Gilger, M.D., Wilmer Ophthalmological Institute of Johns Hopkins Hospital, Baltimore.
9. The Reaction of Various Types of Fat Transplanted into the Orbit of Guinea Pigs Prior to the Development of Exophthalmos. George K. Smelzer, Ph.D., College of Physicians and Surgeons, Columbia University, New York.
10. Conjunctivitis with Membrane Formation. Michael J. Hogan, M.D., Division of Ophthalmology, University of California Medical School, San Francisco.
11. Studies of the Physiology of the Eye Using Tracer Substances. Walter S. Wilde, Ph.D., Roy S. Scholz, M.D., Dean B. Cowie, Ph.D., Carnegie Institute of Washington, Department of Embryology, Baltimore; Wilmer Oph-

thalmological Institute of Johns Hopkins University and Hospital, Baltimore; and Carnegie Institute of Washington, Department of Terrestrial Magnetism, Washington, D.C.

12. Observations on Pityrosporum Ovale in Seborrheic Blepharitis and Conjunctivitis. J. S. Gots, M.D., Phillips Thygeson, M.D.; M. Waisman, M.D., University of Pennsylvania, Philadelphia; University of California, San Francisco; and Tampa, Florida.

Reception

(5:30 P.M.)

Reception for Participants in the Program at the Marlborough-Blenheim Hotel.

PERSONALS

Dr. Frank W. Newell is now located at 30 North Michigan Avenue, Suite 1618, Chicago 2, Illinois.

Dr. Samuel M. Bloom has his offices at 121 East 60th Street, New York 22, New York.

Dr. Joseph I. Pascal of New York gave a series of lectures for the residents and internes of the Department of Ophthalmology, U. S. Naval Hospital, St. Albans, New York, during March. The subjects discussed by Dr. Pascal were: "A Study of Ocular Torsions," "Memory Aids in Physiological Optics," and "The How and Why of Cross-Cylinder Tests."

FIG. 1 (NEWELL). APPEARANCE OF THE EYE SIX WEEKS AFTER THE SECOND PROCEDURE.

EXTENSIVE TRAUMATIC IRIDODIALYSIS WITH REPAIR*

FRANK W. NEWELL, M.D.

Chicago, Illinois

Separation of the ciliary border of the iris from its attachment may occur spontaneously in atrophy of the iris root or may follow blunt ocular contusions in which the iridodialysis is frequently associated with hyphemia, zonular rupture, subluxation of the lens, cataract, and ciliary-body detachment followed by atrophy. The traumatic type may vary in extent from a small defect visible only with a slitlamp to a detachment of the entire ciliary border with the iris falling to the bottom of the anterior chamber and visible as a small gray ball of tissue.

Small defects, those covered by the lids, and asymptomatic cases do not require operative treatment; whereas, large defects causing monocular diplopia, dazzling of vision, and photophobia should be corrected surgically if the concomitant ocular pathologic processes do not overshadow the iridodialysis. Since cases of large separation unaccompanied by other major pathologic conditions of the eye are relatively rare, this case is presented to illustrate a simple method of correction whereby gratifying functional and cosmetic results were obtained.

CASE REPORT

When the patient, a 24-year-old white soldier, was admitted to the 108th General (U.S.) Hospital, December 2, 1943,

* From the Department of Ophthalmology, Northwestern University Medical School.

he stated that 48 hours previously he had been struck in the left eye by a small branch of a tree which caused immediate and severe ocular pain. He was immediately hospitalized, 1-percent atropine solution was instilled in the eye, and a binocular bandage was applied. Vision, two days after the injury, was 20/20 in the right eye; and 20/50 in the left eye. It could not be improved with correction. The only apparent damage to the left eye was a separation of the entire nasal attachment of the iris extending from the 10- to the 7-o'clock meridian. The iris was drawn toward the intact temporal attachment, and only the temporal portion of the pupil was visible. The free iris border appeared to float in the anterior chamber, but it was not possible to change its position by gravity. Intraocular pressure was 18 mm. Hg (Schiotz-Gradle); peripheral and central visual fields were normal; the cornea and conjunctiva did not stain with fluorescein; and the fundus was normal. A slight hyphemia was present immediately after injury, according to the station hospital record, but this had absorbed without residue prior to admission. The chief complaint was dazzling and photophobia in bright light which was not relieved with tinted lenses. Treatment with 1-percent atropine solution, instilled locally four times daily, gave no evidence of response.

On December 8, 1943, the first of a

two-stage operation was performed with O'Brien akinesia and retrobulbar procaine-hydrochloride and topical pontocaine anesthesia. A small conjunctival flap was prepared and a corneoscleral suture was placed at the limbus at the 2-o'clock meridian in such a manner that it could be tied over the cornea instead of the sclera. A small keratome incision was made between loops of the suture, and the peripheral border of the iris was grasped with an iris hook and drawn into the wound. With an assistant drawing up the suture while the hook was simultaneously disengaged from the iris, it was possible to incarcerate a small shred of tissue in the wound without prolapse. The previously prepared conjunctival flap was then drawn over the wound; the episcleral sutures were tied; and pilocarpine solution instilled. A binocular dressing was applied.

Convalescence was uneventful and all sutures were removed on the seventh postoperative day. The iridodialysis was reduced to about one half extending from the 2- to the 7-o'clock meridian.

On January 14, 1944, a similar procedure was performed with the keratome incision at the 5-o'clock meridian, with immediate restoration of a central round pupil and an anterior chamber of normal appearance. Three small peripheral defects were present between the areas of attachment but, as they gave rise to no symptoms, further surgery was considered inadvisable.

Vision was 20/30 in the treated eye, improved to 20/20 with a $-0.75D.$ sph. $\odot +1.00D.$ cyl. ax. 130° . Intraocular pressure was 22 mm. Hg (Schiotz-Gradle). The peripheral field, central field, and accommodation were normal. The pupillary reaction to light was present only in the normally attached segment of the iris but the response of the pupil to miotics and mydriatics appeared nor-

mal. In April, 1945, 16 months after the second operation, in response to a questionnaire the patient replied that corrected vision was 20/20 and J1, the iris was still in position and no further hospitalization had been required.

DISCUSSION

Reattachment of an iridodialysis occasionally occurs spontaneously even in the absence of active ocular therapy. In an early case (1830), Lawrence¹ reported recovery occurring after venesection. Vigorous atropinization of the injured eye has been recommended by Shedlow² and Brown³ who each reported a case in which this treatment resulted in recovery. Duane⁴ considered atropine unnecessary and attributed the fortuitous outcome to recurrent hemorrhages, with the formation of a fibrinous exudate which bound the iris in place. Such a result must be uncommon, however, for Wagemann,⁵ in a comprehensive review of the subject, found only a few cases in which medical treatment was efficacious.

Surgical correction of iridodialysis may be conveniently divided into three main classes: (1) Iridectomy or iridotomy. (2) Reattachment to a fresh surface within the anterior chamber. (3) Incarceration of the iris in a corneoscleral wound.

Middlemore⁶ suggested converting the two pupils into one by dividing the intervening portion of iris, but it is not clear whether he ever performed such an operation. Würdemann,⁷ in at least one case, performed an iridectomy to remove a band of iris stretching across the visual axis and recommended the procedure. Recent publications have not mentioned this type of surgery, and it is probable that it has been generally abandoned.

Jameson⁸ developed an ingenious method of repair in which a fine silk suture is introduced into the sclera, 2 or 3 mm.

behind the limbus, and passed into the anterior chamber. The base of the detached iris is then transfixated, and the suture passed through the cornea where the needle is removed. Through a keratome incision, a small hook then engages the suture between the iris and the cornea, drawing it through the cornea into the anterior chamber and out through the ocular wound where it is tied. The iris then reattaches at the point of contact with the sclera. In the present case, it would have been necessary to perform the maneuver a number of times since the ciliary border of the iris was so distant from the nasal limbus that it was not possible to transfix the iris by using a needle of customary size.

Incarceration of the iris in a corneoscleral wound was originally suggested by Amédée,⁹ in 1865, and the technique has been modified by a number of surgeons, the chief variation being the use of sutures between the iris and sclera as in the methods of Key¹⁰ and Spaeth.¹¹ The amount of iris incarcerated varies

from actual prolapse as in the methods of Smith¹² and Bulson,¹³ to the inclusion of only a small shred of iris tissue as recommended by Goldfelder¹⁴ and Wheeler.¹⁵

Correction of the defect in the present case was essentially the technique of the last two surgeons with the exception of the use of a corneoscleral suture, which by causing immediate closure of the wound insured incarceration of the iris and permitted full control of the amount of tissue included in the wound. Apparently the iris tends to be drawn toward its normal attachment, and actual prolapse is not a complication to be feared.

SUMMARY

A case of extensive traumatic iridodialysis is presented in which a successful functional and cosmetic result was obtained by incarceration of a shred of iris tissue in a corneoscleral wound closed by suture.

EPIDEMIC RETROBULBAR NEURITIS IN THE PHILIPPINES DURING THE JAPANESE OCCUPATION*

GEMINIANO DE OCAMPO, M.D., CARLOS V. YAMBAO, M.D., PABLO J. MAÑAGAS, M.D.,
AND CARLOS L. SEVILLA, M.D.

Manila, Philippines

This report is impelled by two recent articles in ophthalmic literature—"Nutritional Amblyopia in American Prisoners of War Liberated from the Japanese," by Bloom and others¹ and "Ocular Lesions in Internees at a Civilian Internment Camp at Hongkong," by Talbot.² Although these authors agreed on the role nutritional deficiency had in causing the ocular symptoms observed, they differed in their reports of the manifestations of disease and in their interpretations as to the site of the lesions as well as to the deficient vitamin or vitamins. This report is based on studies made on Filipinos who suffered from retrobulbar optic neuritis which occurred in epidemic proportions in the Philippines during 1942 and 1943. While our observations and interpretations may vary from those of others who have reported on the ocular manifestations of nutritional deficiency, we hope that these studies may contribute to a proper evaluation of the factor of the "soil" in the etiologic consideration of optic-nerve lesions of nutritional or other origin.

According to Fernando³ this Philippine epidemic commenced soon after the war; reached the maximum height of incidence about December, 1942, one year after the occupation; and had practically disappeared by the end of September, 1943. Although the records of the Philippine General Hospital show that 451 cases of retrobulbar neuritis were diagnosed in 1942 and 1943, in contrast to 72 cases in

1940 and 1941, this report is confined to the study of 28 cases in which examination and follow-up were unusually thorough, both extremely difficult procedures at that time.

In using the Comberg slitlamp especial attention was given to retroillumination in the study of limbal vascularization. The Ferre-Rand perimeter and the Bjerrum tangent screen were used. A white-ring fixation object was found to give the most accurate records especially in mapping the bilateral central scotomas present in these cases. Ophthalmoscopy was always done under mydriasis to permit careful examination of the macula. Following the advice of Traquair,⁴ the presence of a scotoma was ruled out only by 1/2,000 white and 1/1,000 red or blue test objects. Filipino standards for visual fields and blind spot were first established before interpretations of field changes were made. Refraction was carefully checked in each case.

CASE REPORTS

Before summarizing our findings we shall cite two cases typical of the 28 cases studied.

Case 1. A woman, aged 28 years, complained of foggy vision in both eyes for one week. Positive scotoma, lacrimation, and photophobia were not present. For one month she had had angular stomatitis, and two days before she was first seen she had circumoral numbness. Her diet consisted mainly of rice and fish, meat occasionally, and vegetables rarely.

Examination showed nose, teeth, and tonsils to be normal. The Wassermann

*From the Department of Ophthalmology and Otolaryngology, College of Medicine, University of the Philippines.

test was negative. There were no helminth ova in the feces. The eyes were normal externally. Fundus and biomicroscopic examinations showed no pathologic conditions. Vision was: O.U., 20/30; with the pinhole (2 mm.), no change. Near vision was: O.D., 14/21; O.S., 14/28, made worse by use of the pinhole. There were relative central scotomas for 3/1,000 red in both eyes. There was also bilateral concentric contraction, more temporally, of the peripheral fields for form.

The patient was advised to change her diet and to take a plate of mongo (a native bean) at each meal supplemented by leafy vegetables. She also took darak (rice bran), two tablespoonfuls in a glass of water with orange (citrus mitis blanco) and sugar, 10 times a day. Three months later, vision in both eyes was normal for far and near. The scotomas had disappeared, and visual fields were normal. During the eight months this case was followed, normal vision was maintained.

Case 2. A man, aged 26 years, had progressive blurring of vision and photophobia in the right eye for two months before he was first seen. Three weeks later the left eye showed the same symptoms. No lacrimation, pain, positive scotoma, nor numbness of the extremities were present. Three weeks before visual symptoms appeared, the patient had bilateral, angular stomatitis. The diet was poor, especially in vitamin B.

Examination showed the Wassermann test to be negative. No helminth ova were present in the feces. Teeth, nose, and tonsils were normal. The eyes showed no external abnormality. The fundi were normal. Biomicroscopy revealed a clear cornea, marked limbal pigmentation, and practically normal limbal vascularization in both eyes. Vision was: O.U., 20/50 and 14/42, unchanged by use of the pinhole. There was no manifest refractive error. There was a large bilateral cen-

trocecal scotoma for 1/1,000 white. Visual fields were normal.

The patient in this case was also advised to change his diet. He also began taking "tiki tiki" (rice bran extract) a tablespoonful, three times a day. A week later, his vision had deteriorated to: O.D., 20/160, 14/89; and O.S., 20/50, 14/56. After that, however, it continued to improve. After one month, vision was: O.U., 20/20, 14/35, with very marked subjective improvement. After nine months, vision was normal for far and near and no scotoma was present.

SUMMARY OF FINDINGS

The youngest patient in the series studied was 15 years of age, and the oldest was 60 years of age. The average age was 32 years, and the majority of patients were between 20 and 30 years of age. The almost equal number of men and women (15 m.; 13 f.) belonged, generally, to the lower middle class. Although many of them were unemployed, none could be considered destitute. In private practice, this form of retrobulbar neuritis was found even among the well-to-do class.

All except one case (7) had bilateral involvement, both eyes being affected at the same time in the majority of cases. The one unilateral case was seen early when vision was only slightly impaired, 20/30 in the affected eye with a small, relative central scotoma for red. A month after she was first seen, when vision was almost normal again, this patient failed to return.

The primary complaint of all patients was a failure of vision described as similar to that observed when looking through smoke. Except in a few cases the maximum failure of vision was three or four weeks after the onset. Photophobia, which is not the same as glare blindness (Yudkin⁶) was a complaint in one third of the

cases. Five cases (17.6 percent) had laceration with either itching, redness, or smarting of the eyes. Ocular pain, mucoid discharge, dizziness, and the sensation of warmth in the eyes were observed in individual cases. Headache, generally frontal, was present in four cases. Angular blepharitis associated with angular stomatitis was noted in only one case. Bilateral positive scotoma was a complaint of only one case (10).

Angular stomatitis was present at one time or another during the course of the ocular affection in 71 percent of the cases. Symptoms referable to peripheral neuritis, such as numbness around the mouth and of the extremities and paresthesia of the toes, feet, legs, or fingers, hands, and forearm were found in one half of the cases. Glazed tongue was found in 14.7 percent and scrotal pruritis in 7.1 percent. All except one patient had a deficient diet limited to rice and fish. Some diets had a moderate supplement of vegetables, and a few had a little meat. Only slight losses of weight were shown in these cases.

Seven patients were habitual cigarette smokers, and one patient was a tuba (a native alcoholic beverage) drinker. Two patients were lactating mothers; and two had histories of diarrhea for 2 or 3 months before the onset of ocular symptoms. Two patients had a purulent urethritis and one had a gall-bladder disease.

In all except two cases, there were no external signs of pathologic conditions of the eyes. In one case there was a slightly abnormal limbal vascularization, and in another case there was an anterior polar cataract.

The vision in all cases ranged from 20/30 to 2/200 or less. In four patients vision was 20/50 or better; in two, 20/50 to 20/100; in six, 20/100 to 20/150; in two, 20/150 to 20/200. Fourteen patients, or 50 percent had vision of 20/200 or

less. The subnormal near vision present in all cases was not due to accommodative error.

With no exceptions, a scotoma was demonstrable in every case. The scotoma was absolute in 24 cases, and relative, especially to red, in four. There were 19 bilateral central scotomas, and four bilateral centrocecal scotomas. Five patients had a central scotoma in one eye and a centrocecal scotoma in the other eye. In the only unilateral case, a central scotoma was present in the involved eye. The blind spots were normal in one half of the cases. Five of these had definitely enlarged blind spots distinct from the central scotoma in both eyes; while in four cases, the enlarged blind spots merged with the central scotomas and resulted in bilateral centrocecal scotomas. In five cases, there were unilateral centrocecal scotomas with distinct central scotoma and enlarged blind spots in the other eye. We have found that without the use of a white-ring fixation object, it is easy to record a paracentral scotoma when a central scotoma is really present.

Eighteen cases (64 percent) had normal visual fields. Four had temporal contraction of 5 to 10 degrees for form in one or both eyes, and five had temporal contraction of more than 10 degrees. Nasal contraction of 10 degrees was noted in only one case, but no case showed a very marked concentric contraction as reported in the series of Talbot. It will be seen that while a central scotoma was invariably present, enlarged blind spots, distinct or merged with the central scotoma, were recorded in one half of the cases, while only one third had peripheral field changes which were mainly temporal.

Twenty cases (71.4 percent) had normal fundi. Three cases had temporal pallor of the disc, while three other cases had no abnormal change except absent foveal reflexes. Two had hazy media due

to lenticular opacity in one and epithelial corneal dystrophy (de Ocampo⁶) in the other. One had slight congestion of the disc. There were no abnormal biomicroscopic findings in 16 cases (57.1 per cent). Eight showed only moderate to marked limbal pigmentation. One had epithelial corneal dystrophy associated with abnormal limbal vascularization, while another had minimal epithelial corneal dystrophy with limbal pigmentation but no

to the changed diet. The rice bran contributed approximately 6.6 I.U. of vitamin B₁ daily. In addition to the prescribed diet and rice bran, three cases were treated with transorbital diathermy (Birch-Hirschfeld⁷) for 10 minutes daily for an average of 10 days. One case received diathermy and dietetic treatments, while another was given brewers yeast tablets in addition to the changed diet. Of the 12 patients who did not receive

TABLE 1
RESULTS OBTAINED WITH VARIOUS THERAPIES USED IN TREATING RETROBULBAR NEURITIS IN 23 PATIENTS

Treatment Given	No. of Cases	Recovered	Markedly Improved	Moderately Improved	Unchanged	Worse

Diet and rice bran	7	4	1		2	
Diet, rice bran, and diathermy	3		1		1	1
Diet and diathermy	1			1		
Diet and thiamine	1		1			
Diet and brewers yeast	1	1				
Rice bran alone	2		1	1		
Diathermy alone	3		1	2		
No treatment	2			1		1
Summary	23	6 (26%)	6 (26%)	6 (26%)	3 (13%)	2 (8.7%)

vascularization. One had slight abnormal limbal vascularization but no corneal lesion, and one had arcus senilis.

Wassermann blood tests were made in 16 of these cases. All of them were negative. Feces of 5 of 11 patients showed ova of *Ascaris* and *Trichuris trichiura*.

Various forms of treatment were tried. A change of diet with the addition of beans containing around 90 international units of vitamin B₁ (per serving) plus green leafy vegetables was advised in half of the cases. Seven patients were instructed to take a suspension of rice bran with native orange and sugar in addition

any change in diet, five failed to return for sufficient follow-up. Of the remaining eight patients, two received rice bran alone; three, diathermy alone; one, thiamine chloride only (10 mg. daily for 6 days); and two, no treatment, dietetic or otherwise. The results are shown in Table 1.

It may be said, therefore, that in 78 percent of the cases, there was a change for the better and in one case (4.3 percent) even without treatment. In only two cases (8.7 percent) was the condition progressive; and one of these received no treatment at all. In three (13 percent)

the condition was stationary during the period of observation. Although the number of cases which were carefully followed during this epidemic of retrobulbar neuritis is small, it is our impression that the prognosis for the epidemic as a whole was good.

COMMENT

The diagnosis of retrobulbar neuritis was based on the demonstration of a central scotoma when the fundus was normal or essentially normal. We have not, in fact, been convinced that there is a pathologic significance in the absent foveal reflexes except when there are other fundus findings, because this condition is occasionally encountered in normal individuals. When, however, other macular changes are present, such as the stippling and abnormal reflexes found by Bloom, we consider the condition to be one of central choroidoretinopathy. When the relative scotoma for red is more prominent than that for blue, as in these cases, the condition is more likely a retrobulbar neuritis than a retinal lesion such as Talbot considered present in his cases.

We prefer the diagnosis of retrobulbar neuritis to nutritional amblyopia, which is a vague term, or to optic atrophy, because in our series of cases only 13 percent showed an appreciable pallor of the temporal disc, which is an accepted sign of retrobulbar neuritis of some standing. In fact, in a few cases the pallor had progressed to primary optic atrophy. We have called the condition epidemic retrobulbar neuritis because of its occurrence in epidemic form; however, we believe that it was not contagious nor infectious. Oguchi⁸ reported, in 1930, an epidemic of optic neuritis in Japan, axial in type with superficial keratitis, which he attributed to a deficiency of vitamin A.

It will be noted that this epidemic ret-

robulbar neuritis was not only axial but that there were also peripheral field changes in one third of the cases, and blind-spot enlargements in one half. These conditions pointed to involvement of the fibers at the periphery of the nerve as well as in and around the papillomacular bundle. The course of the disease was subacute or chronic in the majority of cases, although the prognosis was good as a whole, especially when the case was seen early, and the nutritional deficiency was sufficiently corrected. There seemed to be a tendency toward improvement even when no treatment or only vasodilator therapy—transorbital diathermy—was given.

That these patients were suffering from deficiencies not only of vitamins but also of protein, carbohydrate, fat, and so forth was beyond doubt. The deficiencies were not so extended, however, as in the cases of those Americans and British reported by Bloom and Talbot, since loss of weight was not marked. The fact that these patients improved or recovered when they received better diets and additional amounts of vitamin B₁ or vitamin-B complex proved only that whatever other etiologic factors were involved, vitamin-B complex and vitamin B₁, which act as catalysts, and vitamin A played a part. Burn⁹ found histologic evidences of a high incidence of nerve degenerative changes among Filipinos even before the war. The epidemic subsided although the food shortage continued. During the later part of the Japanese occupation in 1944, when evidences of nutritional deficiencies were found even among the well-to-do classes, cases of retrobulbar neuritis were uncommon. Even during the epidemic, it was common to find only one member in a family on practically the same diet affected with retrobulbar neuritis. In our series only one instance of the disease occurring in husband and wife

was recorded. Children were exempt from this epidemic.

Statistics on the cause of retrobulbar neuritis in different countries at different times show wide variations (Benedict,¹⁰ Uthoff,¹¹ Langenbeck,¹² and Cibis¹³). One misleading factor in the etiologic consideration of retrobulbar neuritis in general is the tendency to spontaneous recovery in the majority of cases (Duke-Elder,¹⁴ Dunnington,¹⁵ Editors of E.E.N.T. Yearbooks of 1933 and 1935¹⁶). We also noted this tendency to some extent in this epidemic. Focal infection was present in a few of the cases. Syphilis could probably be ruled out by the course of the affection. Of the demyelinating diseases, multiple sclerosis, whose cause is unknown but which leads in the listed causes of retrobulbar neuritis in America and Europe, cannot be definitely excluded as a cause in some of these cases. The bilateral occurrence of the disease is, however, very much against this hypothesis. A sinus etiology usually shows a bilateral lesion with more blind spot changes than axial involvement.

Concerning the nutritional causes of retrobulbar neuritis, there is much confusion in the literature (Elliot,¹⁷ Oguchi,⁸ Moore,¹⁸ Fernando,¹⁹ Johnson,²⁰ Kilgore,²¹ Gordon and Sevringhaus,²² and Veasy²³) as to the role of vitamins B₁, B₂, B complex, and A. Experimentally produced human deficiencies of these vitamins do not cause retrobulbar neuritis as it is found in the clinics. It is generally recognized that the therapeutic effect of vitamin B₁ in neuritis is not specific (Vorhaus²⁴). The factors of the proportion of the deficiencies and of the individual reaction influence the various clinical manifestations of vitamin deficiencies in man.

Retrobulbar neuritis is a neurodystrophic process in which, according to Spersky,²⁵ the history of each individual

nervous system is important. During the Japanese occupation, not only was there shortage of food in the Philippines but there was much emotional strain or trauma on the nervous system of the people. Even in toxic amblyopia, Duke-Elder¹⁴ mentions that during periods of emotional strain, a habitual drinker or smoker may develop amblyopic symptoms.

After taking all these factors into consideration, we believe that more than one cause may have existed in this epidemic of retrobulbar neuritis (Lillie²⁶). In a population that, even before the war, showed a high incidence of nerve degeneration (although not of the optic nerve) from toxic or poor nutritional conditions, this neurodystrophic process of the optic nerve increased, under war conditions, to epidemic proportions directly and mainly because of nutritional deficiency and hypovitaminosis. Although those patients who developed this affection were certainly subjects of multiple hypovitaminosis, clinically or subclinically, and showed prominent extraocular signs of vitamin-B-complex deficiency, the eye lesion of retrobulbar neuritis was probably due to a deficiency of vitamin B₁ (beriberi factor). The few patients who, in addition to retrobulbar neuritis, had some abnormal limbal vascularization probably suffered from an ocular deficiency of vitamin-B complex. In the very few patients who, in addition to affections already named, showed an epithelial corneal dystrophic lesion without abnormal limbal vascularization, an objective ocular vitamin-A deficiency was probably also present. The predisposing factors may have been: (1) the individual and racial nervous system or "soil"; (2) the emotional strain of the war; (3) focal infection, tobacco and alcohol, lactation, other diseases, and unknown factors.

RATE OF DARK ADAPTATION AND REGIONAL THRESHOLD GRADIENT OF THE DARK-ADAPTED EYE: PHYSIOLOGIC AND CLINICAL STUDIES*

LOUISE L. SLOAN, Ph.D.
Baltimore, Maryland

Measurements of the rate of dark adaptation and of the light threshold of the fully dark-adapted eye as indices of vitamin-A deficiency have been extensively studied in recent years. The earlier investigations led to the conclusion that subclinical vitamin-A deficiency, as manifested by such tests, occurs in a high percentage of the population. These reports, however, were soon followed by critical studies which questioned the norms used in diagnosing subnormal light sensitivity and emphasized the many controls necessary to obtain reliable measurements of the light thresholds.

More recent investigations have employed adequately standardized instruments and procedures in measuring light thresholds. These studies, although they do not support the view that vitamin-A deficiency is prevalent in the United States, however, do present suggestive evidence for a cause and effect relationship between vitamin-A intake and the visual threshold for light, particularly the threshold of the fully dark-adapted eye. The evidence is of two types.

1. Many patients with increased light thresholds not associated with organic disease of the eye are improved or restored to normal by vitamin-A therapy.

2. Normal subjects, when placed on a diet low in vitamin A but adequate in other essentials, may show an increase in light thresholds. Individuals vary markedly, however, in the time required to produce a significant increase in the thresholds and in the time required for re-

covery when vitamin A is resumed. These studies have been reviewed in detail by Mandelbaum,¹ Sheard,² Holmes,³ and Nylund.⁴

There is also some suggestive evidence that riboflavin may play a part in the process of dark adaptation, either directly or by influencing the ability to absorb or to utilize vitamin A. Pock-Steen⁵ reported that patients with leiodystonia and sprue complained of poor vision in dim light, and that these symptoms were not influenced by vitamin A but were greatly improved by riboflavin. A patient with Plummer-Vinson syndrome, reported by Pollak,⁶ had markedly impaired dark adaptation which was improved by riboflavin and restored to normal by brewers yeast. Kimble and Gordon⁷ found that some patients with subnormal dark adaptation who were not improved in two months on vitamin A alone were restored to normal when further vitamin A plus riboflavin was given.

Mention has been made⁸⁻¹⁵ of the occasional occurrence of visual-field defects in patients with poor dark adaptation associated with vitamin-A deficiency. The defects noted were detected on routine perimetric examination except in the studies of Weekers and Roussel. They used a special technique in which the extent of the visual field was determined at intervals during dark adaptation. They found that with dark adaptation there was a significant difference in the results for a control group of normal subjects and a group of malnourished patients from European war prison camps.

The purposes of this paper are: (a) to present norms for a new technique of

*From the Wilmer Ophthalmological Institute of the Johns Hopkins University and Hospital.

measuring the light sensitivity, particularly of the retinal rods; (b) to offer further data on individual variations in response to an experimental diet low in vitamin A; (c) to report a series of patients with little or no systemic evidence of vitamin-A deficiency who nevertheless showed elevated light thresholds which were restored to normal either on vitamin A alone or on vitamin A plus riboflavin; (d) to present further data on the relationship between contraction of the visual field in moderate illumination and elevation of the light thresholds of the fully dark-adapted eye.

TECHNIQUE

The visual-field studies were made with a standard Ferree-Rand perimeter. The illumination incident on the perimeter arc is 7 foot-candles; the brightness of the arc, 0.7 apparent foot-candles (approximately 0.7 millilamberts). The instrument used in studying the light sensitivity has been described in previous papers.⁸⁻¹⁶ It differs from those used by other investigators in that measurements may be made in any desired retinal region from center to far periphery. The procedure used in this study is as follows.

1. The eye is exposed for 3 minutes to an adapting field whose brightness is 1,100 millilamberts.

2. The light threshold is determined at intervals during adaptation to darkness, until it shows no further significant decrease. For these measurements of the rate of dark adaptation the 1-degree white test field is placed in the nasal field 15 degrees from fixation.

3. When dark adaptation is essentially complete, usually in 35 to 40 minutes, the light threshold is measured at the fovea and at 18 other locations extending to 50 degrees in the nasal field and to 96 degrees in the temporal field.

4. At the completion of these measurements a photograph of the pupil is taken with photoflash illumination. This is used in correcting the thresholds for differences in size of pupil as explained below.

Individual differences in size of pupil influence not only the effective brightness of the test spot but also that of the adapting field. In measurements of the dark-adaptation curve, rigid standardization of this variable factor can be achieved only by the use of an artificial pupil for viewing both the adapting field and the test field. In this study, because of the practical difficulties in using such a device, no attempt has been made to eliminate this variable in determinations of the adaptation curve. It is, however, feasible to correct the final thresholds of the fully dark-adapted eye for differences in size of pupil.¹⁷ The final threshold, therefore, can provide a more reliable basis for detecting slightly subnormal light sensitivity than the thresholds measured during the course of dark adaptation, particularly in the case of patients whose pupils are fixed either by a drug or by organic changes. In this study the data used in charting the threshold gradient of the dark-adapted eye are corrected to give the equivalent threshold for a pupil 7 mm. in diameter.

VARIATION IN NORMAL SUBJECTS*

In order to make a diagnosis of subnormal (increased) light thresholds, it is necessary to have data, obtained under standard conditions, showing the range of normal physiologic variation. These data should apply to subjects of the ages, levels of intelligence, and so forth likely to occur in the clinical studies. Our normal group comprised 101 subjects whose ages ranged from 14 to 70 years. Fourteen of

*I am indebted to Dorothy C. Leonhardt for testing the normal subjects and making the statistical computations.

the subjects were Negroes. All had clear media; normal pupillary reactions, normal fundi, and corrected visual acuity of 20/20 or better.

The data on rate of dark adaptation are summarized in Table 1. Column 2 gives in logarithmic units the mean value of the threshold after 1, 2, 4, 6, and so forth minutes of dark adaptation. For each subject these thresholds were read from the smooth curve drawn through the experimentally determined points. Column 3 gives for each of the selected times of dark adaptation the standard deviation* of the threshold, S.D. The greatest variation (S.D. equals 0.38) occurs at 12 minutes; the least (S.D. equals 0.24), at 30 and 35 minutes. The distri-

S.D. and $M - 2$ S.D.; and 99.7 percent between $M + 3$ S.D. and $M - 3$ S.D. A threshold between $M + 2$ S.D. and $M + 3$ S.D. may be considered as questionably subnormal, since only about 2.5 percent of normal individuals have thresholds within these limits. A threshold greater than $M + 3$ S.D. for practical purposes

Fig. 1 (Sloan). Rate of dark adaptation after pre-adaptation to 1,100 millilamberts. A 1-degree white test field located 15 degrees from fixation in nasal field. The area between the upper and lower curves includes 95 percent of those tested.

may be accepted as definite evidence of subnormal light sensitivity.

Figure 1 shows the adaptation curve based on the mean values of threshold, as well as the curves for $M + 2$ S.D. and $M - 2$ S.D. The area between the two latter curves defines the region in which 95 percent of the thresholds of normal individuals may be expected to fall. Thresholds close to the upper curve may be considered questionably subnormal and those more than about 0.3 log unit above it definitely so. A distinct break in the course of the adaptation curve occurs after about 8 or 10 minutes of dark adaptation. The time at which it occurs is known as the "transition time." The thresholds prior to the break measure cone response, because during the early stages of dark adaptation the cone thresh-

Horizontal-meridian threshold (average of thresholds at 19 different locations)—4.41.
Standard Deviation—0.25.

1 gives the mean value and the standard deviation of the transition time.

Table 2 and Figure 2 give similar data on the thresholds of the fully dark-adapted eye at 19 different locations in the horizontal meridian. As explained previously, a correction factor has been applied to these values to give the thresholds for a pupil of 7 mm. in diameter. Column 2 of the table gives the mean values of the threshold; column 3, the corresponding standard deviations. The standard deviations indicate that there is greater variability in threshold in the far periphery and at the fovea than in the paracentral regions. The relatively large range of variation at the fovea is probably due in part to the difficulty in maintaining accurate fixation. The pericentral fixation

device, used in measuring the foveal threshold, does not in some patients maintain fixation as accurately as does the luminous red fixation target used for the other measurements.

The last entry in Table 2 gives the mean and standard deviation of the "horizontal-meridian threshold." This is an index of the average threshold level throughout the horizontal meridian and is computed for each subject by averaging the readings at the 19 different locations. The horizontal-meridian threshold gives an evaluation of the general threshold level and should be a sensitive index of any condition producing a generalized rather than a localized decrease in light sensitivity. Figure 2 shows graphically the threshold gradient, or variation in threshold from center to periphery, for the horizontal meridian. Only the values two standard deviations above and below the mean are charted. The mean threshold

Fig. 2 (Sloan). Threshold gradient of dark-adapted eye in horizontal meridian. A 1-degree white test field. The area between the upper and lower curves includes 95 percent of those tested.

lies midway between the two curves shown in the figure. As in Figure 1 these two curves define the region in which 95 percent of the thresholds of normal individuals may be expected to fall.

In previous investigations of the dark-adaptation curves of normal subjects, an increase in threshold with age has been found,^{18, 19} indicating a possible need

for different norms for different age groups. An analysis of our data shows that the increase with age is attributable in part, although not entirely, to the accompanying decrease in area of pupil. When the original threshold measurements are used, without correction for differences in size of pupil, there is a correlation of 0.48 between the horizontal-meridian threshold and the age of the subject. When, however, this correction is applied, thus eliminating the effect of pupil size, a relatively low correlation (0.28) is found between age and light threshold. Further statistical analysis shows that, without correction for size of pupil, the light threshold increases 0.10 log unit per decade. When this correction is made, the increase per decade is only 0.05 log unit. It may be concluded, therefore, that the increase in threshold with age is negligible* when the threshold is corrected for differences in size of pupil.

EFFECT OF A DIET LOW IN VITAMIN A

The effect of a diet low in vitamin A but adequate in all other essentials was studied in five subjects.[†] Cases 1 to 3 received less than 200 I.U. of vitamin A per day, Cases 4 and 5 less than 100 I.U.

Cases 1, to 3. The changes in the horizontal-meridian threshold while on the diet are shown in Figure 3. In Case 1, this threshold increased only from 4.01 to 4.19 log units during the 30 days on the diet. This subject was not available for further tests after a normal diet was resumed. In Case 2, the diet was maintained for a period of 217 days. The high-

est threshold, 4.49 log units, was found in one of the three tests made before the diet was started; the lowest, 4.21 log units, after 195 days on the diet. It may be seen from the graph that there are irregular changes of small magnitude not related in any way to the dietary status. The average threshold based on all 12 tests is 4.35 log units with a mean variation of only ± 0.08 . In these two subjects the rate

Fig. 3 (Sloan). Changes in threshold of three subjects on a diet deficient in vitamin A. The thresholds are the average of measurements at 19 locations in the horizontal meridian. Arrows indicate cessation of diet.

of dark adaptation likewise showed no significant change. In Case 3, while the changes in threshold are also of small magnitude there is some evidence that they are associated with the reduced intake of vitamin A. The drop in threshold during the first 18 days from 4.20 to 3.95 is probably a practice effect. From the 18th day onward there was a slight steady rise. On the 38th and 41st days the thresholds were 4.34 and 4.28 respectively. The changes in the adaptation curve paralleled those in the threshold gradient. After 19 days on a normal diet plus haliver oil, both curves were still about 0.4 log unit above the lowest previous level. Eighteen days later the adaptation curve had returned to its previous level. The threshold gradient was not determined on this date.

* This has been proved only in the case of thresholds for white light. When blue light is used, as in the Hecht adaptometer, the increased absorption of the shorter wave lengths of light by the lens in older subjects may be a factor.

[†] I am indebted to Dr. Lela E. Booher for the opportunity to examine Cases 4 and 5. They are reported as Case 1, and Case 3 in an article by Booher, Callison, and Hewston.²⁰

Fig. 4 (Sloan). Adaptation curves of Case 3. (1) After 18 days on diet deficient in vitamin A. (2) After 41 days on diet. (3) After 37 days on normal diet supplemented by haliver oil.

In Figure 4, the adaptation curves for three dates are charted to show the in-

crease in threshold and subsequent recovery. It should be emphasized that the highest thresholds of this subject were well within normal limits. Consequently, even if the slight changes are considered to be related to the vitamin-A intake, it is questionable whether they can be interpreted as evidence of an actual deficiency in the clinical sense. None of the three subjects while on the diet deficient in vitamin A showed any significant change in the visual fields for a $\frac{1}{2}$ -degree white test object. In Case 2, tests were also made with 1-degree blue and red test objects and likewise showed no change.

Case 4, reported also in a previous paper,⁸ after 42 days on the diet, showed marked elevation of the threshold gradi-

Fig. 5 (Sloan). Case 4. Threshold gradient and visual field of right eye for 3-degrees, 1-degree, and $\frac{1}{2}$ -degree white test objects. (A) After 42 days on a diet deficient in vitamin A. (B) After taking cod-liver oil for 12 days. Note that (A) and (B) on the threshold-gradient graph refer to these same two dates.

ent (about 3 log units) and peripheral field defects in both eyes demonstrable with $\frac{1}{2}$ -degree, 1-degree, and 3-degree white test objects. The limits of the field for blue, tested only for the right eye, were normal, but within these limits there were small areas in which the blue test object disappeared completely. The location of these areas in the different meridians suggested that they were parts of a ring scotoma. The visual fields and the light threshold were normal when redetermined after the subject had been taking cod-liver oil for 12 days. Figure 5 shows the threshold gradient and the fields of the right eye for $\frac{1}{2}$ -degree, 1-degree, and 3-degree white test objects before and after vitamin A was restored to his diet.

Case 5, whose light threshold (horizontal-meridian average) had increased only 0.5 log unit after 91 days on the diet, had at this time defects in the peripheral fields similar to those of Case 4 but less marked. The visual fields of the right eye for a 1-degree white test object, prior to, during, and after the diet are shown in Figure 6. There was no significant change in the field for 1-degree blue.

OBSERVATIONS IN CLINICAL CASES

Of nine patients examined, eight were referred because of visual symptoms suggesting poor night vision, one because of a skin condition suggesting a possible vitamin-A deficiency. With the exception of Case 11, these patients gave no history of any obvious inadequacy in diet. Four of the patients were examined at the Wilmer Institute; five, at the A.A.F. School of Aviation Medicine.* In two cases, the threshold gradient was within the normal range; in one case, close to the borderline normal curve; and in six cases,

definitely above this curve in some or all regions. All nine patients showed significant improvement either on vitamin-A therapy alone or on vitamin A plus riboflavin.

Case 6. This patient was first aware of poor night vision while driving a car in the country at night some weeks after the

Fig. 6 (Sloan). *Case 5*. Visual field of right eye for 1-degree white test object. (1) Prior to diet deficient in vitamin A. (2) After 28 days on diet. (3) After 91 days on diet. (4) After administration of cod-liver oil for 35 days.

birth of her first child. Examination showed that the threshold gradient and the adaptation curve were about 3 log units above the average normal curves (fig. 7). After three months on massive doses by mouth of vitamin A (90,000 I.U. per day), there was definite improvement. It will be noted in Figure 7 that the decrease in threshold was not of the same magnitude in different retinal regions. At 35 degrees in the temporal field, there was no change in the threshold, but at 10 degrees in the nasal field, there was a decrease of 1.5 log units. Since vitamin-A therapy had not resulted in complete recovery, the effect of 10 mg. per day of riboflavin was then tested.

* Cases 10 and 11 have been reported in a previous paper by W. M. Rowland and the author.²¹

Fig. 7 (Sloan). *Case 6*. Progressive changes in threshold-gradient (A) and adaptation curves (B) of right eye. (1) October 18, 1940, prior to therapy. (2) January 7, 1941, after taking vitamin A for 3 months. (3) January 15, 1941, after taking riboflavin for one week. The daily dose was 90,000 I.U. of vitamin A; 10 mg. of riboflavin.

Fig. 8 (Sloan). *Case 6*. Progressive changes in threshold-gradient (A) and adaptation curves (B) of right eye after further therapy with riboflavin. (3) January 15, 1941. (4) January 17th. (5) January 20th. (6) February 26th. Vitamin A was discontinued on January 7th. Riboflavin therapy was started on January 7th; the entire B complex was started on January 20th.

Fig. 9 (Sloan). *Case 6*. Progressive changes in threshold (A) and adaptation (B) curves of right eye during therapy with vitamin A and entire B complex from February 26 to June 1, 1941. (6) February 26th. (7) March 1st. (8) July 14th.

The first week after riboflavin was substituted for vitamin A, there were further improvements, marked in some retinal regions, slight in others. Riboflavin therapy without vitamin A for an additional six weeks (January 15th to February 28th), however, was accompanied by a gradual rise in the thresholds (fig. 8). The effect of treatment with vitamin A plus the entire B complex is shown in Figure 9. It may be noted that, although the adaptation curve measured at 15 degrees in the nasal field showed no significant change after three days, the threshold gradient revealed that there was significant improvement in other retinal regions.

The patient continued taking vitamin A and the B complex from February 26th until June 1st, when she stopped because subjectively her night vision seemed perfectly normal. She returned for retests on July 14th. On this date the adaptation curve was slightly above the borderline normal curve. The threshold, however, continued to decrease after 40 minutes of dark adaptation, reaching its lowest level which was well within normal limits only after 75 minutes of dark adaptation. The threshold gradient, determined after dark adaptation was complete, was close to the average normal curve. On this date, therefore, the only evidence of defective sensitivity to light was a slow rate of dark adaptation with no abnormality in the thresholds of the completely dark-adapted eye.

Figure 10 summarizes the changes in the horizontal-meridian threshold in relation to therapy throughout the entire period that this patient was studied. The visual field of the right eye was tested with $\frac{1}{2}$ -degree white and 1-degree blue test objects on January 15th, February 26th, and July 14th (fig. 11). On January 15th, only the field for blue was contracted but on February 26th the field for

$\frac{1}{2}$ -degree white also showed concentric contraction similar to that noted in Case 4. The defect in the peripheral field found on February 26th but not on January 15th is consistent with the much higher peripheral light thresholds found on the second

Fig. 10 (Sloan). Case 6. Changes in horizontal meridian threshold of right eye.

date. The concentration of vitamin A in the blood plasma, determined only on January 17th and February 26th, was well within normal limits on both dates (202 and 218 I.U. per 100 cc.). If the markedly elevated light thresholds noted on February 26th are considered to be definite evidence of an ocular vitamin-A deficiency, then it must be assumed that such deficiency can exist in association with adequate amounts of vitamin A in the blood plasma.

Case 7. This man, a member of the staff of the medical school, requested a dark-adaptation test because he was having some difficulty in seeing faint images on a fluorescent screen. Although both the adaptation curve and the threshold gradient were within normal limits, it seemed worth while to determine the effect of vitamin therapy. The changes in the horizontal-meridian threshold are shown in Figure 12. There was a temporary improvement with vitamin A alone and a sustained improvement with the ad-

Fig. 11 (Sloan). Case 6. Visual fields of right eye. (A) For $\frac{1}{2}$ -degree white. (B) For 1-degree blue. (3) January 15, 1941. (6) February 26th. (8) July 14th.

dition of riboflavin, similar to that observed in Case 6. The visual fields were not tested. The maximum decrease in threshold was only about 0.3 log unit and the relationship to therapy is therefore somewhat doubtful in this case.

Case 8. This patient was referred by her doctor for light-sense tests because dryness and itchiness of the skin suggested a possible vitamin-A deficiency. The adaptation curve and the threshold gradient (fig. 13) were close to the bor-

Fig. 13 (Sloan). Case 8. Threshold-gradient (A) and adaptation (B) curves. (1) Before treatment. (2) After one month on vitamin A, 200,000 I.U. per day.

derline of normal. The visual field for 1-degree white was normal. Other test objects were not used. After one month of vitamin-A therapy (200,000 I.U. per day) there was definite improvement in the threshold gradient, particularly in the far temporal field where the decrease was more than one log unit. The only significant change in the adaptation curve was a slight decrease in the final thresholds.

Case 9. This patient reported that for several years she had been unable to see as well as others in dim illuminations. The threshold gradient of the left eye was definitely elevated (fig. 14). At 30 degrees in the nasal field, for example, the threshold was 1.6 log units above the average normal value. After she had taken vitamin A for 17 days, a recheck of the thresholds in the nasal field gave essentially the same results at 6 degrees, 10 degrees, and 15 degrees, but at 20 degrees, 30 degrees, and 40 degrees showed a decrease of 0.7, 1.3, and 1.2 log units respectively. The visual fields of both eyes, tested on this date revealed marked

Fig. 14 (Sloan). *Case 9.* Threshold gradient of left eye. (1) Before treatment. (2) After 27 days on vitamin A. (3) After 9 weeks on vitamin A. (4) After 4 months without treatment. The amount of vitamin A per day was not recorded.

concentric contraction for white test objects and moderate contraction for a 1-degree blue test object. The fields of the left eye are shown in Figure 15. After 9 weeks of vitamin-A therapy, the threshold gradient and the visual fields were within normal limits. Four months without vitamin A did not result in any significant increase in the thresholds.

Case 10. Prior to vitamin therapy, the

Fig. 15 (Sloan). *Case 9.* Visual fields of the left eye for 3-degrees white, $\frac{1}{2}$ -degree white, and 1-degree blue. (A) October 24, 1939, after 17 days on vitamin A. (B) December 2, 1939, after 9 weeks on vitamin A.

thresholds were elevated throughout the entire horizontal meridian. The adaptation curve showed a normal rate of dark adaptation with elevation only of the final

units before treatment; 4.5 and 4.2 after three and four months of vitamin therapy.

Case 11. This patient, while subsisting entirely on emergency rations, had lost

Fig. 16 (Sloan). *Case 10.* Threshold-gradient (A) and adaptation (B) curves. (1) Before vitamin therapy. (2) After daily doses of 100,000 I.U. of A, 5 mg. of B₂ for 3 months. (3) After 4 months on this regime.

Fig. 17 (Sloan). *Case 11.* Threshold-gradient (A) and adaptation (B) curves. (1) After taking vitamins A and D, amounts unknown. (2) After 3 weeks on 100,000 I.U. of vitamin A, 8,000 units of vitamin D per day. (3) After 5 weeks during which the B complex including 3 mg. of riboflavin per day was taken in addition to vitamins A and D.

threshold about one log unit above average normal (fig. 16). After daily doses of 100,000 I.U. of vitamin A and 5 mg. of riboflavin for three months the threshold gradient and the adaptation curve were within normal limits. There was further improvement after an additional month of the same treatment. The average horizontal-meridian threshold was 5.5 log

weight and appetite and developed marked symptoms of night blindness. For some weeks prior to our first examination of the patient, he had been on a normal diet supplemented by vitamins A and D in undetermined amounts. His threshold gradient was elevated almost 2 log units above average normal in the para-central nasal field. (fig. 17). After he

had taken 100,000 I.U. of vitamin A and 8,000 units of vitamin D for three weeks, there was definite improvement. The adaptation curve at this time showed an abnormally slow rate but a final threshold close to the borderline normal value. The threshold gradient showed a further decrease five weeks later after treatment with vitamins A, D, and the B complex, including 3 mg. of riboflavin per day.

Case 12. This patient had also taken vitamins A and D prior to the first examination. The thresholds (fig. 18) were elevated in some regions, normal in others. After three months on a regime of 25,000 I.U. of vitamin A and 5 mg. of riboflavin per day, there was definite improvement and the entire curve was with-

Fig. 18 (Sloan). *Case 12.* Threshold gradient curves. (1) After taking vitamins A and D, amounts unknown. (2) After daily doses of 25,000 I.U. of vitamin A, 5 mg. of B₂ for 3 months.

in the normal range. The maximum decrease occurred at 6 degrees in the temporal field where the threshold fell from 5.40 to 4.05 log units.

Case 13. This patient had taken vitamin A prior to the first examination. The threshold gradients of both eyes were determined (fig. 19). That of the right eye was close to the borderline normal curve while that of the left eye revealed much more marked defects in some regions. At 60 degrees in the temporal field, for example, the threshold was 2.4 log

Fig. 19 (Sloan). *Case 13.* Threshold gradients of right and left eyes. (1) After taking vitamin A, amounts unknown. (2) After daily doses of 50,000 I.U. of vitamin A, 5 mg. of B₂ for 3 months.

units above the average normal value. After three months on daily doses of 50,000 I.U. of vitamin A and 5 mg. of riboflavin the threshold gradients of both eyes were essentially the same and were within the normal range.

Case 14. This patient had a threshold gradient (right eye) within normal limits (fig. 20). The left eye was not tested. He had not taken any vitamin supplements prior to the first examination. After 7 and 13 weeks, during which time he took 100,000 I.U. of vitamin A and 5 mg. of riboflavin per day, retests showed a threshold gradient close to the lower normal level, indicating better than average normal sensitivity. The average

decrease in threshold following therapy was 0.8 log unit.

COMMENTS

In two patients in this study (cases 6 and 11) increased rod thresholds during the earlier stages of dark adaptation were observed on one occasion when the final threshold of this same retinal region was within normal limits. In general, however, our findings are in agreement with the accepted view that in vitamin-A deficiency the light threshold of the fully dark-adapted eye is increased earlier and to a greater extent than the thresholds measured during the course of dark adaptation. Our results also show that the final threshold of the dark-adapted eye may be normal in some retinal areas, elevated in others. The improvement which follows vitamin-A therapy may likewise occur earlier or may be more marked in some areas than in others. Tests of the light sensitivity of only a single retinal region may therefore fail to reveal defects or to detect improvement in retinal function following therapy.

Because of the relatively wide range of normal variation in threshold, it is possible for an individual whose optimal threshold gradient is close to the lower limit of normal to have an increase in thresholds of as much as one log unit above his own normal level and still be within the normal range. Two such cases were observed in this study (cases 7 and 14) and were diagnosed as deficient in vitamin A from the fact that significant improvement in thresholds followed vitamin therapy. It has been my experience that subjects with normal thresholds do not as a rule show any significant decrease in thresholds when large amounts of vitamin A are administered. When such improvement does occur, therefore, it is reasonable to suppose that the previous level, although within the normal range,

was not normal for the individual in question.

Of our nine subjects with visual defects responding to vitamin therapy, only one gave a definite history of a previously inadequate diet. In the one case in which determinations were made of the vitamin-A content of the blood, normal values were found in association with fairly marked elevation of the light thresholds. If we accept as evidence of an ocular vitamin-A deficiency elevated rod thresholds which return to normal following therapy, then we must admit that individuals ingesting a diet containing adequate amounts of vitamin A, who have a normal concentration of vitamin A in the blood and no evidence of deficiency elsewhere in the body, can nevertheless have an insufficient supply of vitamin A in the retina or a deficient ability to utilize it.

Conversely it is possible, at least for some individuals, to subsist for many months on a diet containing very little vitamin A, but adequate in other respects, without showing ocular or other evidence of a deficiency. While it is probable that in such subjects the liver reserves are drawn upon to replace what is lacking in the diet, it is not clear why these reserves do not prevent the development of visual defects in other subjects. The possible role played by riboflavin needs further study to determine whether it has a direct effect on retinal function or merely has some influence on the ability of the retina to utilize vitamin A. In 7 of the 9 cases reported in this study, riboflavin and vitamin A were given and in at least one case there is definite evidence that simultaneous use of both vitamins was necessary to restore the thresholds to normal.

Concentric contraction of the peripheral isopters of the visual field without other evidence of pathologic conditions of the eye is often attributed to poor cooperation of the patient, hysteria, and so

forth. The findings of this study suggest that in such cases the possibility of a vitamin-A deficiency should also be considered.

Visual-field studies alone, however, cannot be considered adequate to detect all cases of vitamin-A deficiency. Defects demonstrable by the usual perimetric tests are sometimes, but not always, present when the thresholds of the dark-adapted rods are increased. A close parallel is not to be expected between these thresholds and the extent of the visual field, since the latter is normally determined when the eye is adapted, not to complete darkness, but to a low level of brightness. In the Ferree-Rand perimeter, for example, the brightness of the perimeter arc is approximately 0.7 millilambert. Studies now under way in this laboratory indicate that at this level of light adaptation the rod and cone thresholds of the normal eye in a given retinal region are approximately equal. A significant contraction of the visual field would, therefore, be expected when both cone and rod thresholds were elevated but might not occur when only the rods or only the cones were affected.* Previous studies of the adaptation curve in experimental vitamin-A deficiency^{18, 23} have shown that a slight

increase in the final cone threshold usually accompanies a marked elevation of the rod section of the curve. When visual-field defects are observed in patients with vitamin-A deficiency it is probable, therefore, that the cone as well as the rod thresholds of the far periphery are significantly increased.

SUMMARY AND CONCLUSIONS

1. Data are given showing the range of variation among normal subjects in (a) the dark-adaptation curve of a single retinal region and (b) the threshold gradient of the fully dark-adapted eye in the horizontal meridian of the retina.

2. The same tests were given to five subjects on diets low in vitamin A. Two showed no significant change in the adaptation curve or the threshold gradient after 30 and 195 days respectively on the diet; two showed only slight increase in the thresholds after 41 and 91 days; and one showed a very marked rise in the thresholds after 42 days. Two of the five developed concentric contraction of the visual fields which returned to normal after vitamin A was restored to the diet.

3. Studies were also made of nine patients with elevated light thresholds which were restored to normal following vitamin therapy. The findings indicate that riboflavin in addition to vitamin A may sometimes be required to bring about complete recovery.

4. The results of these studies suggest that concentric contraction of the visual field occurs frequently in patients with ocular vitamin-A deficiency and probably indicates cone as well as rod involvement.

* Confirmation of this is found in the fact that in two cases of typical achromatopsia (a condition in which there is, presumably, complete loss of cone function with normal rod function), I found entirely normal fields for a 1-degree white test object. A case of incomplete achromatopsia, reported previously²² has, in addition, an abnormally slow rate of dark adaptation and an elevated threshold gradient similar to those of patients with vitamin-A deficiency. This subject, who apparently has dysfunction of both cones and rods has also a concentrically contracted field for a 1-degree white test object.

THE INFLUENCE OF GENERAL METABOLIC AND NUTRITIONAL DISTURBANCES UPON THE RESISTANCE OF THE CORNEA

ADALBERT FUCHS, M.D.*
Shanghai, China

The corneal stroma is one of the strongest and most resistant tissues of the human body. Anyone who has made a corneal puncture with a very sharp needle knows how much effort is required to push the needle through the stroma, how the cornea is indented during this procedure, and how the needle becomes anchored within the tissue, which resists advancement of the needle through the cornea.

The cornea is also relatively resistant to infections. Severe purulent conjunctivitis does not always damage the cornea, and there is rarely a bacterial invasion of the stroma in corneal erosion, not even in the recurring type, in which very extensive epithelial defects occur. The most dangerous abrasions and traumas due to small foreign bodies are, perhaps, those which dentists encounter during the removal of calcareous deposits. The smallest lesions of this kind often lead to the most destructive corneal infections.

The relatively great resistance of the corneal stroma to infections is particularly surprising in view of the absence of blood vessels, which in other tissues represent the main defense mechanism. The basis for this unexpected resistance to infection is, on the one hand, the density and compactness of arrangement of the rather firm corneal fibrillae which permit only small amounts of fluid in the interstitial spaces, and, on the other hand, the constant flow of lacrimal fluid which cleanses mechanically and which, through its lysozym content, also has some bactericidal power.

It may be surprising, therefore, that under certain circumstances the resistance of the corneal parenchyma is considerably diminished and that this diminution is due to general metabolic and nutritional disturbances.

CONDITIONS OF LOWERED CORNEAL VITALITY

Various groups of conditions will be discussed in which a lowered corneal vitality and lack of resistance to external damage and infection have been observed.

CASES OF LAGOPHTHALMOS

1. In some cases of complete lagophthalmos, the cornea may remain intact. This is especially true in those instances in which the facial nerve has been severed during operations on the ear or parotid gland. In these cases, the cornea may remain completely exposed during sleep and yet, surprisingly, no hyperemia of the bulbar conjunctiva, no corneal damage, nor increased lacrimal flow develops. Facial paresis from other causes leads more frequently to keratitis e lagophthalmo. Rheumatic facial paresis, however, is soon followed by excessive lacrimation which prevents the drying out of the cornea and the development of lagophthalmic keratitis in a high percentage of cases without other preventive measures.

In some contrast to the above mentioned causes of lagophthalmos there is the congenital, often familial ptosis, with shortness of the upper lids, which prevents complete closure of the palpebral fissure. These patients frequently require a ptosis operation. Great care should be exercised to elevate the upper lid just enough

* Translated by Bertha A. Klien, M.D., 7427 South Shore Drive, Chicago 49, Illinois.

to enable the patient to look straight ahead without having to throw his head backward, because due to the preëxisting shortness of the lids the postoperative lagophthalmos is considerable and leads often to lagophthalmic keratitis in later years. In common cases of ptosis, the postoperative lagophthalmos is of such low degree that it does not often cause complications even in later life.

In all types and degrees of lagophthalmos, even the most complete, the innate vitality and great resistance of the cornea may prevent corneal complications. It is different if the lagophthalmos is associated with general debility and nutritional disturbances, as illustrated by the following cases.

Case 1. A woman, aged 20 years, received antisyphilitic therapy with Salvarsan. Almost immediately she developed a generalized dermatitis and was placed in the continuous bath. Gradually the severely damaged skin was replaced by fine, diffuse, shiny, pink scar tissue, which caused some shrinkage of the lids and a slight lagophthalmos of about 1 to 1.5 mm. In spite of this low degree of lagophthalmos and a normal Bell's phenomenon, bilateral lagophthalmic keratitis with rapidly progressing ulceration developed. Because of the skin condition neither bandage nor moist-chamber dressing was tolerated. One eye was lost following perforation of the ulcer and endophthalmitis; the other eye retained some useful vision in spite of perforation of the ulcer and iris prolapse. During the same period in which I observed this case, two similar cases of corneal destruction after Salvarsan poisoning were reported, one by Hegner¹ the other by Erggelet. Both² patients had severe Salvarsan dermatitis which ended lethally. In one patient, the cornea melted away completely; in the other, circumscribed defects developed which became epithelialized again. In neither pa-

tient was lagophthalmos mentioned, although it probably was present but of such slight degree that it was overlooked by the dermatologist.

Such rapid dissolution of the cornea does not occur in the ordinary cases of mild lagophthalmos, unless a severe nutritional disturbance due to poisoning and general debility is associated with it.

Another kind of low-grade lagophthalmos is not unusual in moribund patients. Although usually not more than 1 or 2 mm. of the cornea are exposed, lagophthalmic keratitis is not too rare in these patients. Most of the histologic specimens of this condition in my collection are from such patients. Perforation of these ulcers is rare, as the patients usually die before it occurs. The following case is of this type, and will be discussed in detail because it proves that it is indeed the general debility which predisposes to this rapid corneal disintegration and because it gives some useful hints for effective therapy.

Case 2. A man, 58 years of age, suffered a severe attack of pneumonia in addition to a nervous disorder with disturbances of equilibrium. When I first saw him, he was completely apathetic and was lying as if moribund with incompletely closed palpebral fissures. There was marked bilateral ciliary injection of the lower bulbs, and corneal infiltrates (1 by 3 mm.) had developed near the lower limbus in both eyes. Therapy for two weeks with atropine, oxycyanate of mercury (1:4,000 solution), and boric acid ointment did not improve the ocular condition. The general condition of the patient also remained unchanged. I then ordered daily intramuscular injections of Vogan (vitamin A). When I saw the patient again a week later, he was sitting up in bed; the bulbs were pale, and shiny facettes had replaced the former corneal infiltrates.

This case of lagophthalmic keratitis in a critically ill patient responded strikingly to intramuscular vitamin-A therapy although no outward signs of avitaminosis were present. The severe illness had caused general nutritional disturbances in spite of the adequate food intake. The injections proved strikingly beneficial not only upon the ocular but also upon the general condition.

CEREBRAL HEMORRHAGE AND CORNEAL DISEASE

2. A different type of corneal disease is illustrated by the following case.

Case 3. An old woman had suffered a cerebral hemorrhage followed by paralysis of the right side. There was marked general debility and severe pulmonary congestion due to myocardial degeneration. There was a marked spastic entropion of the lower lids, and in the right eye the inverted cilia had caused a corneal perforation with iris prolapse and purulent iritis instead of the superficial keratitis more common in this condition.

In this case the severe general disease had led to the unusual complications of corneal perforation and iris prolapse in a spastic entropion. There was, apparently, not only an unusual lack of resistance of the corneal stroma but also a decreased corneal sensitivity; otherwise, the patient would have directed the attention of the attending physician toward the eye sooner.

MARANTIC CORNEAL ULCERS

3. Marantic ulcers of the cornea are closely related to the above mentioned cases. These ulcers develop in debilitated patients with such severe hepatic diseases as carcinoma or cirrhosis. They are flat, rather torpid ulcers, which do not change their appearance rapidly, cause only mild ciliary injection, and are accompanied by a stringy conjunctival secretion. The bul-

bar conjunctiva has often the appearance of tissue paper and, occasionally, Bitôt's spots, which have the appearance of dried soap foam, develop in the interpalpebral area, just as in keratomalacia and hemeralopia. These patients are usually icteric and their scleras are yellow. In severe cases, such marantic ulcers may lead to destruction of the cornea.

The corneal lesions in the two groups of cases described above are not due to lack of vitamin A in the food but to lack of utilization of the ingested vitamin. There appears to be a barrier between the intestinal tract and peripheral organ and intramuscular administration of vitamin A would seem to be a logical and promising therapy.

KERATOMALACIA

4. Closely related to the marantic ulcer is keratomalacia. It is mostly a disease of poorly nourished, ill, and weakened babies, and therapy with vitamin A is general.

It is considered by many, and in my opinion justifiably so, as a primary necrosis of the corneal lamellae with secondary invasion of bacteria from the conjunctival sac. Such eyes appear dry; the lacrimal fluid is diminished and its mechanically cleansing and bactericidal influence is, therefore, lacking.

The cause of this nutritional disturbance of the cornea is a generalized metabolic disturbance, often not a real lack of vitamin A but a lack in certain tissues of proper utilization of the vitamin and its metabolic derivatives. In the eye, the bulbar conjunctiva, cornea, and pigment epithelium are affected. The conjunctiva becomes dry and looks like wrinkled tissue paper, and Bitôt's spots appear. In the cornea, there develops a large, rapidly disintegrating infiltrate; the disturbance of the pigment epithelium manifests itself in hemeralopia. The finer and rarer lesions,

such as pigmentation of the cornea and white punctate lesions of the fundus, will not be discussed here.

A patient, whom I saw and treated in 1927, at a time when no parenteral vitamin therapy was as yet available, demonstrated that at least in some cases lack of utilization of the vitamin and not lack of its ingestion is responsible for keratomalacia.

Case 4. A baby, six weeks of age, was fed partly with mother's milk, partly with cow's milk, and looked well in general. Four days prior to the first visit, bilateral opacities were noted. At the time of this visit, there was already a small perforation in the lower half of each cornea and marked xerosis of the conjunctiva. Ultra-violet irradiation of back and abdomen was begun immediately, at first for three minutes a day at a distance of 60 cm. The feeding remained the same. Gradually the time of irradiation was increased. On the fifth day, the mother's breasts and the cow's milk were also irradiated. Within three weeks, the conjunctival xerosis had disappeared, the ulcers were healed, the anterior chambers restored, and the child, who had also suffered during this time from severe bronchitis, had gained 700 gm. It appears that the amount of vitamin already present in the milk became somehow activated and effective through the irradiation.

Another illustration in favor of poor utilization of the vitamin rather than its actual lack is the distribution of keratomalacia in India. I found keratomalacia widely distributed throughout Asia, from Palestine to Japan, occurring sometimes in children 5 and 6 years of age, but mostly in babies. In Japan about 20 per cent of blindness is due to this disease. However, in the state of Mysore in India, which is an especially well-governed district where one gets the impression of a high standard of living, keratomalacia is not infrequent in pregnant women or soon after parturition. These women of-

ten lose the sight of both eyes, while their babies develop neither xerosis nor keratomalacia. They frequently do not belong to the poorer classes and seem well nourished. I have neither seen nor heard of similar cases in any other province of India.

These cases show clearly, in my opinion, that there is not merely a simple lack of vitamin A, but a disturbance in the utilization of the vitamin. The ulcer in keratomalacia is not characterized by invasion of any one type of bacteria; therefore, the assumption that one is dealing primarily with a nutritional disturbance of the cornea as the consequence of a general metabolic disturbance is justified.

BASEDOW'S DISEASE

5. In rare instances of Basedow's disease, the proptosis is so marked that the lids no longer cover the cornea, and lagophthalmic keratitis develops. In these cases one attempts to protect the cornea by a moist-chamber dressing, a tarsorrhaphy, or, in severe cases, by a tenotomy of the levator palpebrae in order to release the severely retracted upper lid.

The severest degrees of exophthalmos sometimes follow a thyroidectomy, appearing from two months to a year after the operation, and are often associated with papilledema, retinal lesions, and impairment of vision. In these cases it is indicated to remove the roof of the orbit and of the optic canal and sever the tendon ring of Zinn. The exophthalmos may diminish in the course of several months. Naffziger³ found in these cases a waxy and hyalin degeneration of the muscle fibers and some infiltration of the muscles with lymphocytes and plasma cells. In these cases the cornea is damaged not only through desiccation but also through a nutritional disturbance. The latter is partly general and partly local. It is caused by the marked exophthalmos which is accompanied by severe chemosis

and swelling of the lids. The cornea may melt away rapidly in spite of a moist-chamber dressing, and it is in these seemingly hopeless cases that Naffziger's operation may be advised.

Case 5. A woman, 35 years of age, suffered from Basedow's disease and had lost 30 pounds. Professor Kaspar, who performed the thyroidectomy, found part of the gland liquefied and the fluid, which was under pressure, spouted a meter high after the section. During the night following the operation, severe dyspnea necessitated a tracheotomy. Several months after the operation, the already proptosed eyes became still more prominent and a tarsorrhaphy was performed. This was not tolerated by the patient for long, as the chemosis and exophthalmos increased further. The left cornea melted away rapidly and, in the fourth postoperative month, the right cornea also began to show infiltration in spite of a meticulously applied moist chamber and therapy with Vogan and pituitary preparations. At this stage, I saw the patient for the first time. There was maximal proptosis and chemosis of the bulbar conjunctiva. In the right cornea, there was an ulcer 5 by 6 mm. in size, whose margins showed yellowish infiltration and whose floor bulged forward. The pupil was maximally dilated, but there was no hypopyon. The left cornea had already melted away, and the left eye was very soft. I advised irradiated milk and Anthithyreoidin. I heard later that the right ulcer perforated but did not progress so that portions of the cornea were preserved. The left eye developed an apphation of the cornea and became blind.

In this case I did not advise Naffziger's operation because the corneal damage was so advanced, had progressed so rapidly, and the corneal ulcer in the better eye was just about to perforate.

Undoubtedly the rapid disintegration of the cornea was partly the consequence

of the severe local circulatory disturbance, and partly due to the severe general toxic condition of the patient.

ECZEMATOUS CONJUNCTIVITIS

6. In very run down and anemic children, eczematous conjunctivitis sometimes leads to destructive corneal ulcers. These ulcers are not caused by infection, and it is difficult to explain them solely on an allergic basis, which presumably is the main factor in eczematous conjunctivitis. I often saw such corneal infiltrates and ulcerations in adults whose general health was below par. In these patients, who are usually quite anemic, underweight, and often have multiple lymphomas, the generally weakened physical condition seems to be responsible for a diminution of the resistance and vitality of the cornea, as the following case illustrates.

Case 6. A man, 40 years of age, sustained a severe pulmonary injury during the war and was operated for empyema. The patient was in a generally feeble condition and undernourished. There was eczema of the face and eyelids and a marked bilateral conjunctivitis, associated in the right eye with a corneal infiltrate and in the left eye with a small, deep, crater-shaped ulcer. The eczema was successfully treated with cehasol paste, the conjunctivitis with oxycyanate of mercury and novargan ointment, but the ciliary injection of the bulb remained the same in spite of intensive atropine medication, which did not succeed in dilating the pupil appreciably within two weeks. Finally, I ordered pyramidon, 0.2 gm., six times daily. After two days, the ocular condition had improved considerably; the eyes could be opened; the bulbs were pale; and the corneal ulcers were cleansed and epithelialized. The eczema of the face had disappeared completely. The pyramidon medication was discontinued, but within two days, the ciliary injection of the bulbs reappeared and the left, already epithe-

lialized, crater-shaped ulcer had perforated, leading to a small iris prolapse.

The condition of the eyes was such as one encounters not infrequently in cases of severe eczema of the face, and which resembles eczematous conjunctivitis. The fact that an ocular condition of this type is so refractory might be due to an altered mode of reaction of the entire ectoderm of the body. The unusual and late perforation of the already cleansed ulcer was probably not due to allergy but to a diminished vitality of the cornea in the course of the debilitating general illness. In this case the prompt effect of the cumulative doses of pyramidon is also noteworthy.

In the therapy of eczematous keratitis, one obviously has to distinguish between measures which are directed against the allergic condition of children and adolescents, in whom often a simple foreign body elicits a typical attack of eczematous conjunctivitis with phlyctenules and pannus, and the general hygienic measures as mud and seabaths, and cod-liver oil, iodine, iron, and quinine medication which, by raising the general physical resistance, also increase the vitality of the cornea.

DISCUSSION

In these six groups of cases there is a diminution of corneal resistance due to a general weakening of the connective tissue of the body, and it is interesting to point out analogous conditions in other parts of the body.

There is the reopening of the postoperative wound and evisceration after abdominal surgery. Large, collective statistics show that this occurs in 2 to 3 percent of all laparotomies, and is almost twice as frequent in men as in women. It occurs predominantly in patients who suffer not only from the current surgical condition but also from general cachexia, acute or chronic toxic conditions, or considerable

anemia (Hofstätter⁵). Other predisposing diseases are diabetes, syphilis, and avitaminosis. Many authors have reported this surgical complication as occurring in years of famine and as more frequent at certain times of the year, late winter and early spring, when nutrition becomes poorer. Only in rare instances is this reopening of abdominal wounds ascribed to faulty suturing technique or inferior suture material. Most authors believe that a diminished "tissue tone," delayed healing tendency, or "tissue paralysis" due to general debility are responsible for it.

I believe that there is an inherent weakness, fragility, and striking lack of resistance of the connective-tissue fibrillae rather than an absence of healing tendency.

The frequent occurrence of hernias in times of famine has a similar pathogenesis; that is, general damage to the connective tissue apparatus. These hernias have become very common during the past few years and often occur in people who have remained physically fit through continuous gymnastic exercise. Many surgeons consider the rapid and considerable loss of weight and the consequent loss of lipoid tissue in the abdominal wall as the cause of these hernias. It is, however, not very obvious how lipoid tissue should strengthen the abdominal wall to such an extent. It is more probable that, in the course of marked loss of weight due to malnutrition, the connective-tissue fibers are weakened and that this leads to thinning and dehiscences especially in such places of naturally weaker resistance as the inguinal canal. The pathogenesis of the above discussed manifestations of corneal and of general disease appear to be the same; namely, a striking diminution of the vitality of the connective-tissue apparatus.

SCLERAL NECROSIS IN PERIARTERITIS NODOSA

A CASE REPORT*

FRED HARBERT, CAPT. (MC), U.S.N.,

AND

SAMUEL D. McPHERSON, JR., LIEUT. (JG), (MC), U.S.N.R.

Philadelphia, Pennsylvania

Periarteritis nodosa was first described by Rokitsansky in 1852.¹ In 1866, Kussmaul and Maier described the gross and microscopic pathology of the disease. Since that time more than 550 cases have been reported and of these only 10 percent exhibited ocular involvement.^{2,3}

Goldsmith has recently reviewed the ocular signs of periarteritis nodosa.⁴ These include papilledema with optic atrophy, involvement of the choroidal vessels, involvement of the retinal vessels with the formation of fusiform aneurysms, retinitis with retinal detachments, hemorrhages and exudates, recurrent vitreous hemorrhages, and involvement of the extraocular muscles.⁵⁻¹¹ A survey of the literature reveals no report of scleral necrosis occurring in the course of this disease.

REPORT OF A CASE

G. H., aged 31 years, was first admitted to the U. S. Naval Hospital at Philadelphia on April 11, 1946, with the complaint of weakness, headache, and anorexia. The

present illness apparently began two years prior to admission when the patient, an enlisted man in the Army, developed an acute otitis media and abscess of the nasal septum. While under treatment with sulfonamides, the patient developed what was thought to be an allergic reaction to them. One blood culture out of many prior to treatment was reported positive for hemolytic staphylococcus aureus. The patient recovered from this acute episode with considerable nasal saddleback deformity due to loss of cartilage, chronic right dacryocystitis, and deafness, which necessitated the use of a hearing aid. In February, 1945, he developed an interlobar collection of fluid in the right chest and an exacerbation of chronic dacryocystitis. Cultures and guinea-pig inoculations of the pleural fluid were reported negative. Both lesions cleared with penicillin therapy, and the patient was asymptomatic until just prior to admission.

PHYSICAL EXAMINATION

Positive findings on admission were an interlobar collection of fluid in the right chest, chronic right dacryocystitis with fistula formation, marked saddleback de-

* Read at College of Physicians of Philadelphia, Section on Ophthalmology, October 24, 1946.

formity of the nose, large perforation of the nasal septum, and marked atrophy of all turbinate tissue with nasal crusting and tendency toward spontaneous epistaxis. The right ear drum was markedly retracted with recent vascularization, and the left drum showed an old perforation with adherence of the drum margins to the medial wall of the middle ear. Re-

Fig. 1 (Harbert and McPherson). Right eye. Showing extensive, sharply demarcated, superficial necrosis surrounded by chemotic conjunctiva. Cornea clear.

peated sputum examinations were negative for tubercle bacilli and careful study showed no evidence of active pulmonary infection. Vision was: O.D., 20/20; O.S., 20/15. No pathologic condition of the eyes was noted. The patient desired a nasal plastic operation, and a dacryocystectomy with excision of the fistulous tract was performed on May 1, 1946, as a preliminary to rhinoplasty.

COURSE

The immediate postoperative course was uneventful; the wound apparently healed by primary intention, and sutures were removed on the fourth postoperative day. At this time the patient developed edema of the right eyelids. On the seventh postoperative day, he developed photophobia, lacrimation of the left eye, and a bilateral, superficial, punctate keratitis which persisted in spite

of local treatment with hot compresses and the administration of intravenous typhoid vaccine. On the 14th postoperative day, the patient developed a spontaneous subconjunctival hemorrhage in the right eye at the 1-o'clock position, just outside the limbus. The following day this lesion became edematous, and a similar lesion appeared in the left eye. Within 48 hours, both lesions ulcerated, and the patient developed spontaneous epistaxis. Smears and cultures were taken from both lesions for aerobic and anaerobic bacteria, acid-fast bacilli, and fungi. These were all repeatedly negative except for an occasional colony of diphtheroids. Direct scrapings were taken from both lesions and the nasal mucosa and stained for tubercle bacilli and ordinary bacteria. These were likewise negative.

The conjunctival and scleral necrosis continued to progress until a "porcelain white," completely avascular slough developed (figs. 1 and 2). The patient was treated locally with penicillin drops and systemically with 30,000 units of penicillin every three hours. There was very little change in the patient's condition, although 21 days after the onset of the ocular disease, an occasional vessel could be seen appearing in the area of the

Fig. 2 (Harbert and McPherson). Left eye. Similar lesion of left eye.

slough. One month after the onset, the patient was given streptomycin (2 gm. daily for 5 days), with no apparent effect on the slow healing process. After cessation of the streptomycin, the patient became febrile, spiking a temperature of 99° to 100°F. at irregular intervals. Repeated blood cultures taken during the febrile period were negative.

At this time the eyes first showed some definite evidence of improvement. Conjunctival epithelium began to cover the scleral sloughs which had become so deep that uveal pigment could be seen shining through. At the same time, from the marginal conjunctiva, vessels began to invade the sloughing sclera and adjacent cornea to form a superficial pannus (fig. 3). The patient complained of paresthesia of both hands and developed a persistent eosinophilia of 8 to 10 percent, albuminuria (1 plus to 3 plus), and microscopic hematuria. The sedimentation rate was

Fig. 4 (Harbert and McPherson). Right eye. Showing early stage of secondary scleral nodule.

PATHOLOGIC REPORT

The pathologic report of T. W. Bennett, Comdr. (MC), U.S.N.R. is as follows.

Sections from the gastrocnemius were studied (fig. 5). In areas in the muscle fibers, there was evidence of low-grade inflammatory change. In one area between the muscle fibers, there were cross sections of several small blood vessels. These vessels were identified as arterioles. In one, there was practical occlusion of the lumen of the vessel. The intima appeared to be missing, and there was an apparent thrombosis with beginning canalization. About this area, there was proliferation of connective tissue and a zone of round cells, polymorphonuclear leukocytes, plasma cells, and occasional eosinophiles. In another area there appeared to be complete thrombosis and organization resulting in fairly dense fibrous tissue. About this area there was evidence of chronic inflammation. Another vessel was seen which appeared to have proliferative changes in the intima and subintimal area. About this area there was a moderate amount of chronic inflammatory change characterized especially by the presence of plasma cells. It is believed

Fig. 3 (Harbert and McPherson). Right eye. Showing superficial pannus vessels and vascularization of central area of slough.

27. Blood Kahn and spinal-fluid examinations were negative. In view of these findings it was thought advisable to perform a muscle biopsy to exclude periarteritis nodosa. This was done in the seventh week of the ocular disease.

that these sections represent three stages: (1) Beginning proliferative changes in the intima, (2) complete thrombosis with occlusion of the vessel, and (3) complete thrombosis with beginning canalization of the thrombotic area. These findings are

ophthalmoscope and slitlamp. The vitreous now became hazy, and a beam without cells appeared in the anterior chamber, 11 weeks after the onset of ocular symptoms. Shallow necrotic ulcers also developed on the buccal mucosa. Multiple

Fig. 5 (Harbert and McPherson). Typical periarteritis in muscle biopsy.

consistent with those occurring in periarteritis nodosa.

SUBSEQUENT COURSE

In the eighth week of the ocular disease, the patient developed redness, pain, and swelling of the right ankle which was considered due to vascular occlusion followed by a similar lesion of the left wrist in the 10th week. The wrist lesion suppurated. The corneoscleral lesions relapsed, the necrosis extending into the cornea. Prior to this time, the ocular media were clear to repeated examinations with

vitamins, including riboflavin, failed to influence the course of the disease. Twelve weeks after the onset of ocular symptoms, the patient developed intradermal nodules on both feet and legs. Biopsy of one of these showed typical lesions of periarteritis nodosa (fig. 6). This diagnosis was confirmed by Dr. Arnold R. Rich of Johns Hopkins Hospital.

Fundus details were not now visible. The margins of the original scleroconjunctival slough were not healed, but the central portion showed a thin scar with uveal pigment showing through. The up-

per margin of the cornea developed superficial sloughs which coalesced to form an ulcer with an overhanging edge extending toward the central portion of the cornea in the manner of a Mooren's ulcer.

superficial slough at the site of injection. Intradermal desensitization with 1:1,000 staph toxin was given for a month with no evidence of favorable response, and the patient was discharged from the hos-

Fig. 6 (Harbert and McPherson). Typical periarteritis with thrombosis in skin biopsy.

There was scattered, superficial, corneal vascularization. Both corneas became edematous. The left eye developed several large keratic precipitates. Vision was: O.D., 1/200; O.S., 2/200.

Since the patient had responded to no other therapy, and in view of the previously reported positive blood culture for staphylococcus aureus, the patient was tested intradermally with staphylococcus toxin to determine his sensitivity. He was found to be mildly positive to 0.1 cc. of 1:1,000 dilution; and very markedly positive to 0.1 cc. of 1:100 dilution. With the 1:100 dilution, the patient developed a

pital at his own request 15 weeks after the onset of the ocular disease.

COMMENT

A clinically similar type of ocular lesion has been described as anterior metastatic scleritis. According to Duke-Elder, this is usually due to a staphylococcal embolus (90 percent), but occasionally is due to pneumococci.⁵ In a few cases, no organisms were found.

The fundamental pathologic change in periarteritis nodosa is inflammation of the medium and small arteries with fibrinoid hyaline necrosis and exudative processes.

As the necrotizing process subsides in one organ, it may involve another with remissions and relapses. Many etiologic explanations have been suggested but the most widely accepted one is that it is not a disease entity, but a hypersensitivity of the arterial walls. It is most often related to a bacterial allergy in chronic infections, but experimental evidence indicates that drugs, foreign proteins and serums, and even foods or pollens may be responsible. Since the widespread use of the sulfonamides, the number of cases reported has

increased markedly. These drugs are presumed to act as haptens, combining with plasma proteins to form allergens.²

SUMMARY

A case of scleral necrosis occurring in the course of periarteritis nodosa is reported and discussed. No treatment was of any avail despite the establishment of the diagnosis early in the course of the disease.

NEUROBLASTOMA OF THE ADRENAL WITH ORBITAL METASTASES*

REPORT OF FIVE CASES WITH AUTOPSY FINDINGS

ROBERT N. SHAFFER, M.D.

San Francisco, California

The purpose of this paper is to add to the ophthalmic literature five proved cases of neuroblastoma of the adrenal with orbital metastases and to record the therapeutic failure of radioactive phosphorous as a method of controlling this fatal tumor of childhood.

HISTORICAL REPORT

Sympathetic neuroblastomas of the adrenals were recognized by Marchand¹ in 1891, who described them as being of neural origin. In 1910, Wright² confirmed Marchand's findings and established the tumors as clinical entities. Meanwhile two distinct clinical types had been described. In 1901, Pepper³ reported an adrenal tumor which he called a congenital sarcoma that invaded the liver and regional lymph nodes, causing stillbirth or death in early infancy. In 1907, Hutchinson⁴ described a similar adrenal tumor in children up to 15 years of age, but which metastasized early to the orbit, meninges, skull, and long bones. It is this, the Hutchinson type of neuroblastoma, which is of particular interest to the ophthalmologist.

CLINICAL PICTURE

The most common 'symptom which brings these patients to the ophthalmologist is a recurrent area of ecchymosis about one or both eyes, often thought to be of traumatic origin. This ecchymosis is soon accompanied by a firm, bony swelling somewhere about the orbit, which frequently results in proptosis and dis-

placement of the globe, and which may reach the proportions of a malignant exophthalmos. Corneal ulceration and secondary infection can cause the loss of an eye.

Early in the disease, the primary tumor is rarely palpable. Enlargement and extension to adjacent lymph nodes frequently produce an upper abdominal tumor later. Metastases are commonly found in the skull and long bones, but their presence in liver, lung, lymph nodes, and so forth emphasizes the lack of a clean-cut differentiation between the "Pepper" and "Hutchinson" types. Subjective symptoms depend on the location of the metastases. If these occur in the skull, increased intracranial pressure is common, with headache, nausea, vomiting, choked discs, separation of suture lines of the skull bones, and hydrocephalus. If metastases appear in the vertebrae and long bones, pain may occur in the back and extremities. One case⁵ has been reported with multiple skin nodules present at birth. No sexual changes are ever noted such as are found in tumors of the adrenal cortex. General symptoms of weight loss, pallor, low temperature elevation, anemia, and a low leukocytosis are present.

A provisional diagnosis of neuroblastoma can be made from these symptoms. Confirmation must be obtained by biopsy and by X-ray studies. Biopsies can be taken from any area of metastasis or from the primary growth. X-ray studies of the involved bones show multiple, tiny foci of resorption, giving a finely granular osteoporosis with uneven density of the skull and pelvis. There may be local or

* From the Division of Ophthalmology, University of California Medical School.

extensive involvement of the long bones with elevation of the periosteum and metastatic areas of resorption in the ends of the diaphyses adjacent to the epiphyseal lines. Pyelograms show a normally functioning kidney often displaced downward. An important finding that is not usually mentioned is the presence of flecks of calcification in the primary tumor just above the pole of the left kidney.

ETIOLOGY AND PATHOLOGY

Embryologically the medulla of the adrenal gland is formed by the undifferentiated nerve cells of the primitive sympathetic nervous system. It is a failure on the part of these cells to mature that results in neuroblastoma of the adrenal. Although congenital, the time of onset of symptoms may be delayed as much as four years after birth, varying with the malignancy and the location of the metastases in the individual case. In the Hutchinson type, the tumor is in the left adrenal gland. Since the liver and lungs may both escape involvement, metastases are thought to spread by way of the fetal blood and lymph circulation. The only other alternative would be the spontaneous development of multiple primary tumors in various parts of the body.

Pathologically the tumor is made up of firm pink tissue, which cuts with a gritty feel, due to areas of calcification. The surface is mottled by hemorrhagic areas, as one would expect in a neoplasm of so vascular an organ as the adrenal. The thin-walled capillaries are the source of the orbital ecchymoses which so often are the first sign of the disease. The cells tend to be small and round, with dense hyperchromatic nuclei and but little cytoplasm. These are similar to the primitive migrating cell of the sympathetic nervous system. A few larger round cells with vesicular nuclei, and some pear-shaped cells

resembling spongioblasts can be seen. In 30 to 50 percent of specimens, the small cells group in solid masses or hollow spheres, called "rosettes." All the cells give off delicate processes which unite to form a fibrillar syncytium (fig. 3).

Although the usual microscopic picture is conclusive, it may be very confusing. As stated by Wahl:⁶ "Because the adrenal neuroblastomata are so malignant and composed of the sympathetic formative cell, any transition may be present between the primitive cell and chromaffin and ganglion cells." The various transitions may cause parts of the tumor to resemble glioma, scirrhous carcinoma, lymphosarcoma, or sarcoma. For years the tumor was thought to be a retroperitoneal sarcoma. Two of our five cases were misdiagnosed after a biopsy had been studied. It is, therefore, important that the entire clinical picture be considered, and that a microscopic diagnosis be obtained from competent pathologists.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of neuroblastoma may be difficult due to the varying areas of metastatic involvement and to the infrequent finding of an abdominal tumor. The age group of the patients, in itself, limits the diagnostic possibilities. Careful blood studies will differentiate neuroblastoma from the blood dyscrasias which can produce ecchymosis and proptosis. However, aleukemic leukemia can produce a similar bony resorption in the skull without characteristic blood findings. Scurvy causes ecchymosis and X-ray studies of rickets will show subperiosteal proliferation. The dietary history and general physical findings should eliminate these diseases, however. Hemangiomas about the orbit will not produce this type of X-ray picture. Chloroma is a tumor which involves the flat bones, but its diagnosis is relatively easy because of a typical

microscopic and blood picture. Other neoplastic diseases are rare in children.

COURSE OF THE DISEASE

The disease progresses steadily, irrespective of therapy. Pain is usually not severe and often is entirely absent. New metastatic foci appear, and the old areas continue to enlarge. Weakness and anemia become more prominent. As is common in neoplasms of children, the general health remains fairly good, with rapid failure in the few weeks before death. Patients rarely live more than one year after the first symptoms appear. Farber⁷ reported that 10 out of 40 patients with neuroblastoma were alive 3 to 8 years after diagnosis had been made, but these patients did not have the Hutchinson type. He states that in every case with skull metastases, death resulted.

TREATMENT OF THE DISEASE

X-ray therapy has been the only agent of any particular value in controlling neuroblastomas, and its effects have been temporary. To my knowledge, radioactive salts have not previously been used in this condition. Two cases of the five herein reported were treated with radioactive phosphorous in the form of sodium hypophosphate which had been prepared in the cyclotron of the University of California. Case 1 was given large doses of the radioactive salt by mouth, a total of 5.3 milluries being given without effect. Case 2 was given a large single dose of radioactive phosphorous, intravenously. If tumor cells selectively pick up these salts, large concentrations can be demonstrated over the site of the tumor by the Geiger counter. In this patient, results were encouraging the first day. The count of radioactivity showed a definite concentration over the tumor site on the right orbit as compared to the control area on the left orbital rim. This initial difference rapidly diminished. By the next day, radioactivity

was the same on one side as on the other. The initial difference was thought to be due to the increased vascularity of the tumor area. This type of treatment is of no value unless the salts are stored in the tumor cells, as occurs in thyroid cells when radioactive iodine is injected. The use of radioactive phosphorous in the treatment of neuroblastomas must, therefore, be recorded as a failure in these two cases.

X-ray treatments are of great help in controlling the size of the individual metastatic lesions. Their use may avoid a progressive exophthalmos which can cause the loss of an eye as occurred in two of the six reported cases. X-ray therapy also has an immeasurable psychologic value both for the parents and the patient, even though it may not prolong life. Deep X-ray therapy is usually applied in divided dosages over a period of two months. The tumor should be irradiated from two directions, each field receiving a total of 2,000r to 3,000r. Treatment other than X ray is entirely palliative. The anemia which appears in the later stages of the disease can be benefited by treatment with iron and liver, and by blood transfusions, though these only postpone the inevitable outcome.

CASE REPORTS

Of the six cases of neuroblastoma reported, five were of the Hutchinson type, and one, Case 6, proved at autopsy to be a neuroblastoma whose origin was high in the cervical sympathetic chain. In all six cases, ecchymosis about the orbit and proptosis were present, and they were the presenting complaints in two cases. Two of the six patients eventually lost an eye because of extensive exophthalmos. Ages in this group varied from 4½ months to 4 years. One patient lived 2½ years after the onset of symptoms, but the others died in 4 to 12 months.

Fig. 1 (Shaffer). Case 2. Neuroblastoma of the left adrenal with metastasis to right orbit.

CASE 1

History. G. A. R., a white boy, aged 10 months, had as chief complaint a mass in right upper quadrant. His history showed that he was jaundiced for five days postpartum and had a rather large head. At the age of four months, he developed a slight difficulty in breathing, and at six months, a mass in the right upper abdominal quadrant was palpated. In the next three months, ecchymotic areas appeared about both eyes, and lumps developed on both temples and on the left shoulder.

Physical examination showed ecchymotic areas about the right eye and subconjunctival hemorrhages in both eyes. A large, firm abdominal tumor mass could be palpated in the right upper quadrant, and a small one was noted in the left supraclavicular fossa.

Laboratory findings. Blood tests. re-

ported: Red blood corpuscles 3.8 million; hemoglobin, 84 percent; white blood corpuscles, 8,000; normal distribution. Urine tests were negative.

X-ray studies showed moth-eaten areas in both frontal bones, in the intertrochanteric area of the left femur, and in both tibias. No calcification was seen in the abdominal mass. A biopsy of the supraclavicular mass revealed neuroblastoma.

Course of the disease. Doses of 700r of X ray were given to the frontal area. Metastases increased in size and in number. Proptosis developed. Hemoglobin dropped from 85 to 54 percent. Large doses of X ray seemed to have no effect on the tumor. A total of 5.3 millicuries of radioactive phosphorous was given by mouth without improvement. The patient died one year after onset of symptoms. At autopsy it was seen that the tumor was seeded throughout skull, long bones, a few ribs, and the abdominal and thoracic lymph nodes. In this case the liver was also heavily invaded, and there was scattered invasion of the pancreas. Microscopically, the cells were typical of neuroblastoma.

CASE 2

History. T. F., a three-year-old white boy, was seen because of recurrent subcutaneous ecchymosis of the right eye.

Physical examination revealed a low, rounded swelling of the right frontal bone extending from the lateral orbital rim halfway up the forehead. The eye was slightly proptosed, and pushed downward and inward. A faint ecchymosis of the right upper lid could be seen. No diplopia could be elicited. The fundi were normal.

Laboratory findings. A blood count showed red blood corpuscles, 3.69 million; hemoglobin, 75 percent; white blood corpuscles, 13,700 normal distribution. Urine tests were reported negative.

X-ray studies revealed a roughening and thickening of the right superior orbital rim, with small areas of rarefaction in the frontal bone. A bone survey was otherwise negative. Above the left kidney, which was normal by intravenous pyelography, was a $1\frac{1}{2}$ by 1 cm. ringlike calcification. The lungs were slightly hazy.

The clinical diagnosis was neuroblastoma of the left adrenal.

Course of the disease. The left adrenal was removed surgically to prevent further metastases. No local metastases were noted. Grossly and microscopically the tumor was typical of a neuroblastoma.

Radioactive phosphorous was injected intravenously, but no selective retention of the salt by the tumor was shown. Deep X-ray therapy to the skull resulted in a

definite shrinkage in the size of the tumor mass. Six months later, a similar mass in the left temporal fossa responded similarly to X ray. Terminally, a progres-

Fig. 2 (Shaffer). Case 2. Adrenal tumor after surgical removal.

Fig. 3 (Shaffer). Photomicrograph of neuroblastoma showing rosettes.

sive anemia developed with low fever and weakness. The patient died suddenly one year after the onset of symptoms.

CASE 3

History. P. B., a girl, aged $3\frac{1}{2}$ years. After a normal infancy, the patient began to have an intermittent fever of 103°F . four months before entry. She complained of pains in the neck and legs.

Physical examination. A firm mass was felt in the left upper abdomen; otherwise the examination was negative.

Laboratory findings. Blood tests showed: red blood corpuscles, 3.2 million; hemoglobin, 60 percent; white blood corpuscles, 7,800; distribution, normal.

Urine, spinal fluid, tuberculin test, blood cultures, and various agglutination tests were all negative.

X-ray studies showed a rarefaction and some periostitis of both femora and humeri. A ringlike area of calcification, 3 by 4 cm. in size, was seen in the abdomen just lateral to the left lumbar spine between the 11th and 12th posterior ribs.

A bone-marrow biopsy reported: blasts, 1.6 percent; myelocytes, 0.4 percent; metamyelocytes, 1.4 percent; nonfilamented, 2.4 percent; filamented, 0.6 percent; eosinophils, 0.2 percent; lymphocytes (mostly young), 89 percent; and nucleated red blood corpuscles, 4 percent. A lymph node biopsy was negative. The tentative diagnosis was aleukemic lymphatic leukemia.

Course of the disease. The intermittent fever continued. Some swelling about the eyes and on the legs appeared. Veins on the skull became prominent and a cracked-pot resonance of the skull could be obtained. The optic discs were found to be choked, with an elevation of about 3 diopters. X-ray pictures showed extensive separation of the skull sutures, mottling of the skull bones, and extension of long-bone involvement. A blood count showed 3.17-million red blood corpuscles with 55-percent hemoglobin; 10,000 white blood corpuscles; and normal distribution. Neuroblastoma of the left adrenal was proved at autopsy.

CASE 4

History. G. L. J., a boy, aged 20 months, was seen because of an intermittent rash and fever for 15 months. An erythematous rash first appeared on the face, neck, and chest at the age of five months. It was associated with a fever of 100° to 101°F. every few weeks and with a slight anemia.

Physical examination. A large firm mass could be palpated in the abdomen in

the left upper quadrant. Otherwise, the examination was negative.

Laboratory findings. Blood test reports: red blood corpuscles, 4.7 million; hemoglobin, 76 percent; white blood corpuscles 12,200; normal distribution. Urine tests were negative.

X-ray studies showed a partially calcified abdominal and retroperitoneal tumor which caused a bulge of the left psoas muscle and downward displacement of a normal left kidney.

Course of the disease. A large mass was removed from the abdomen. Lymph nodes along the vena cava were seen to be involved. The tumor cut with a gritty feel, and the cut surface was mottled yellow, red, and blue with small gritty particles of calcium scattered throughout. Pathologically the cells were typical of neuroblastoma.

One month after entry, rarefaction of the left frontal skull was seen by X ray, and deep X-ray irradiation was instituted. A total of 1600r was given front and back over the skull, lower mediastinum, and upper abdomen.

The patient was not seen for two years and was in good health during this time. Then, a 4 by 5 cm. swelling, lateral to the left eye, appeared, and the patient developed irritability, leg pains, and fever. The blood picture at this time was not remarkable. X-ray studies showed further rarefaction of the skull, left tibia, pelvis, and, perhaps, the vertebra and supra-orbital plate. Weakness increased, and he died 2½ years after the onset of the first symptoms.

At autopsy, many white nodules were found in the pancreas, right adrenal, preaortic and mediastinal nodes. The left adrenal had been removed in the previous surgery. The testes, dura, and skull bones, as well as the tibia were involved. Microscopically the cells were typical of neuroblastoma.

CASE 5

History. C. D., a girl, aged nine months, had shown dark areas around her eyes for two months.

Physical examination. Firm, bony swellings of the skull were present—two in the right occipital region, 2 by 2 cm. in size; one above the right ear 2 by 2 cm. in size, pushing the ear downward; and a 2 by 5-cm. mass in the left temporal region. Marked ecchymosis was present about both orbits, and there was pronounced exophthalmos, more marked on the right. The spleen could be felt 6 cm. below the costal margin.

Laboratory findings. Blood: red blood corpuscles, 3.28 million; hemoglobin, 70 percent; white blood corpuscles, 17,350; normal distribution. Urine tests were negative.

X-ray studies showed irregular destruction of the skull bones. The facial bones were practically destroyed. An osteolytic process was present in the lower three fourths of the tibia. The clinical diagnosis was chloroma.

Fig. 4 (Shaffer). Case 5. Neuroblastoma of left adrenal with multiple metastases.

Fig. 5 (Shaffer). Case 6. Neuroblastoma of cervical sympathetic chain.

A biopsy from one of the skull lesions was obtained, and a pathologic diagnosis of myeloma was made.

Course of the disease was steadily downhill. Both femurs and tibias showed extensive bony destruction, and the skull lesions progressed. Exophthalmos became more marked. A corneal ulcer, which appeared on the right eye, subsequently perforated. The child died two months after entry and four months from the time of onset of symptoms.

An autopsy revealed a typical neuroblastoma of the left adrenal with metastases to the regional retroperitoneal, iliac, and inguinal lymph nodes. Practically every bone in the body was riddled with tumor. A single nodule was present in the liver.

CASE 6

History. S. J., a 4½-months-old girl was seen because of the prominence of both eyes. At the age of 2½ months, she had developed a nasal discharge and occasional vomiting. At 3½ months, both eyes had become prominent, and fixed in the sockets.

Physical examination. Bilateral proptosis was present, more marked on the right, and there was no light reaction in

either eye. The fundus veins were engorged, the discs were elevated 2 diopters, and some exudate could be seen. The roof of the mouth appeared thickened. The fontanels were open and very tense. No abdominal mass was palpable.

Laboratory findings. Blood count was: red blood corpuscles, 5.4 million; hemoglobin, 70 percent; white blood corpuscles, 16,800; normal distribution. Urine tests were negative.

X-ray studies showed a total destruction of bone lying between the nasopharynx and the sphenoid, extending into the posterior ethmoid sinuses and the floor of the middle fossa on both the right and left sides. No signs of abdominal tumor were present. The provisional diagnosis was chordoma. A biopsy diagnosis was neuroblastoma. The revised diagnosis was neuroblastoma of the adrenal with metastases.

Course of the disease. The symptoms increased rapidly, and on terminal hospital entry, at the age of one year, the left eye was pushed completely out of the orbit onto the cheek, and was atrophic and desiccated. The right eye was pushed down and out. A baseball-sized mass filled

and protruded from the mouth. The child died 10 months after onset of symptoms.

At autopsy, no involvement of the adrenal was demonstrated. The lungs were studded with metastases. The whole central skull was involved in the tumor mass. Histologically, the tumor was demonstrated to be a neuroblastoma. Its origin was in the region of the superior cervical ganglion. The final diagnosis was neuroblastoma of the superior cervical sympathetic ganglion.

SUMMARY

Neuroblastomas of the adrenal gland of the Hutchinson type are discussed. Five case reports with autopsy findings are given. One case, with an identical clinical picture, had its point of origin high in the cervical sympathetic chain. Radiologic evidence of calcifications above the left kidney at the site of the primary tumor is an extremely important clinical aid in diagnosis. This finding has been insufficiently emphasized in the past. The use of radioactive phosphorus has been unsuccessful, up to this time, in the treatment of these cases.

PAPILLEDEMA AND PAPILLITIS*

MAX CHAMLIN, M.D.
New York

The clinical and pathologic differences between papilledema and papillitis were clearly defined by Paton and Holmes¹ in 1911, but ophthalmologists are still debating the issue. In 1942, Bedell² reported six cases of papilledema without increased intracranial pressure. Lillie³ and Verhoeff⁴ raised the question as to whether Bedell's cases were really papilledema or optic neuritis, and the subject was fully discussed. The point is that as recently as 1942, there was still dissension as to the differential diagnosis between papilledema and papillitis.

In using the term papillitis. I refer to optic neuritis with involvement of the intraocular portion of the optic nerve so that exudates and hemorrhages are seen on and around the disc. This is in contrast to retrobulbar neuritis, which is optic neuritis of a more posterior portion of the nerve, and which, in the early stage, produces no ophthalmoscopic visible evidence. When optic neuritis is mentioned in this article, it means optic neuritis with papillitis.

When one is confronted with a swollen disc, hemorrhages, exudates, and venous engorgement, one must differentiate between papilledema and papillitis. Of course, if the history, the clinical and neurologic pictures, X-ray air studies, lumbar punctures, and electroencephalograms point to a definite intracranial mass, there is usually little or no problem—one is most likely dealing with papilledema. Such cases are not apt to cause confusion. It is in those early cases in which the studies are inconclusive that the ophthalmologist is faced with the problem of dif-

ferentiating between papilledema and papillitis. An early diagnosis of papilledema in such cases may help to bring early surgical intervention and, thereby, save life.

To help in this differential diagnosis, we must utilize the fundusoscopic picture, the study of visual acuity, and studies of the central and peripheral fields.

The differential diagnosis of papilledema and optic neuritis was well described by Aiken and Cordes.⁵ I wish to mention a few words about the fundusoscopic picture and to emphasize especially the importance of the visual-acuity and the field studies.

FUNDUSCOPIC PICTURE

Many of our recent textbooks contain valuable differential fundusoscopic pictures of papilledema and papillitis. However, I believe that many ophthalmologists will concede that the ophthalmoscope alone will not always give a clean-cut differential diagnosis. I have often found the application of these differentiating points rather difficult in the many cases of papilledema and optic neuritis seen at Montefiore Hospital. Not all cases of papilledema have the typical mushroom appearance of the swollen disc projecting into the vitreous. Many of the cases show a diffuse blurring of the disc margins caused by exudates extending into the peripapillary retinal layers, with hemorrhages or exudates, arterial narrowing, and venous engorgement. This produces a picture so much like optic neuritis that a differential diagnosis becomes almost impossible. Unilaterality or bilaterality are sometimes used as criteria but, although papilledema is more often bilateral and optic neuritis unilateral, one does see uni-

* Work done under the William L. Hernstadt Fund, Ophthalmological Service, Montefiore Hospital for Chronic Diseases, New York City.

lateral papilledema in the early stage and optic neuritis is occasionally seen bilaterally.

VISUAL ACUITY

The history of loss of vision may often be helpful in deciding whether the case is one of papilledema or optic neuritis. It has been stated that a history of sudden loss of visual acuity speaks for optic neuritis while gradual or little to no loss of visual acuity points to papilledema. Let us scrutinize this statement for its pitfalls. Often the word "sudden" must be evaluated carefully. For example, a patient may say that he has suddenly lost vision in an eye when he really means that he has suddenly become aware of the fact that his vision was poor in that eye. Actually, he may have had papilledema for quite a long time, with some spread of edema to the macular area and a gradual reduction in central vision.

On the other hand, the patient may say that he merely has a slight blurring of vision, that he can actually read 20/20. Such a case, at the bedside, would make one think of papilledema. Still, this picture may be that of a case of optic neuritis with a paracentral scotoma and retention of 20/20 vision. The paracentral defect may cause only a slight diminution in central visual acuity (case 1). In fact, one may see a nerve-fiber bundle defect with complete sparing of central vision (case 2). Of course, cases of these two types are not common. Case 2, demonstrating a nerve-fiber-bundle defect in optic neuritis, is probably rare. Since such cases do sometimes occur, however, the possibility of their presence must be borne in mind.

Sudden loss of vision, although classically denoting optic neuritis, can actually be the patient's description of sudden awareness of a gradual loss of vision in papilledema; and good central visual

acuity can be retained in optic neuritis with paracentral defects. From this discussion it is apparent that a study of the central fields on the tangent screen assumes paramount importance in making a differential diagnosis between papilledema and optic neuritis. This emphasis on the study of visual fields seems timely in view of Cordes's recent plea for a more extensive understanding of perimetry.⁶

VISUAL-FIELD STUDIES

The classical field picture of papilledema is that of an enlarged blind spot. In optic neuritis, however, there is a central or paracentral defect, together with some enlargement of the blind spot and peripheral depression. Here again we encounter pitfalls, both in the examination and its evaluation.

One must remember that in early papilledema, the enlarged blind spot is surrounded by a zone of relative field defect, corresponding to the "sloping edge" of Traquair. This pericecal zone of relative defect probably corresponds to that portion of the peripapillary retina whose percipient elements, while not completely pushed aside, have been sufficiently encroached upon by the edema and pressure as to diminish their sensitivity.

When this area of relative field defect is wide enough, as in marked or rapidly spreading papilledema, it will involve, temporally, the macular area, and produce a relative central scotoma. However, to differentiate this from the central or cecentral defect of optic neuritis, we find that, in papilledema, the relative scotomatous encroachment on the central area is just the temporal portion of a general pericecal involvement, the relative scotoma reaching rather uniformly around the entire enlarged blind spot.

In optic neuritis, on the other hand, the central or paracentral defect, if connected with the cecal area, is more apt to

be connected by a comparatively narrow bridge of field defect, so that the overall picture will be that of an area shaped like a dumb bell. It may, perhaps, simulate the cecocentral defect of tobacco amblyopia. It is likely that this cecocentral communication will be lost in time. It may be that, at the start, the central or paracentral defect will show no connection with the enlarged blind spot.

In those cases of macular or paramacular involvement, in which it is difficult to tell whether the central defect is due to the spread of edema from papilledema or to an independent paracentral defect fusing with an enlarged blind spot, it has been found that when the density of the defect keeps on diminishing from the cecal area to the point of fixation papilledema is present; while, in papillitis, as the cecal area is approached, some areas of increased density again appear. If the findings are not sufficiently clear or convincing, the central fields must be followed daily. In cases of papillitis, the central defects are apt to become separated from the cecal defect within several days, the enlarged blind spot is likely to diminish in size (fig. 2 A, B, and C), and the central defect to persist as a discrete scotoma (fig. 2 B and C). In papilledema, however, the enlarged blind spot persists and even increases in size, the central defect continuing to be part of the general pericecal involvement. In other words, after a week or two, papilledema will still show a preponderance of defective field around the blind spot; while in papillitis, the greater amount of defect will persist around the fixation area.

As a rule, the connecting cecocentral portion of the scotoma of papillitis is apt to be less dense than the central one, but the relative densities of these areas may be difficult to evaluate. A careful search of the paracentral area should be made. If small enough visual angles are used,

one may find small, dense areas within larger, less dense areas. This will help to establish the diagnosis of optic neuritis. In cases of this sort, quantitative perimetry assumes great importance. For example, if the enlarged blind spot is mapped out with 10/2,000 white and no central defect is found, an examination with 2/2,000 white may bring out a central or paracentral defect, with or without a cecocentral connection. One must bear in mind that early cases only are being discussed. If a case of papilledema is several months old, some central defects may have developed. Also, one must bear in mind that there are central scotomatous defects in neoplastic lesions around the chiasma, such as in the series of cases of suprasellar meningioma recently described by Schlezinger, Alpers, and Weiss.⁷ However, in the early stage, neoplastic lesions are not likely to show papilledema, and the clinical picture is more apt to be confused with that of retrolbulbar neuritis rather than with that of papillitis.

According to Traquair,⁸ one should be able to differentiate macular involvement in spreading papilledema from the central involvement of optic neuritis by the different colors of test objects. Retinal involvement from papilledema should give a defect for yellow and blue; while direct involvement of the optic nerve should cause more defect for red and green. I have been unsuccessful in duplicating all these findings in a number of cases, but have found white test objects of small sizes very useful for quantitative evaluation. Red test objects are, however, useful in determining the relative densities of nerve involvement in scotomatous areas. The patient will often give a descriptive response of the hazy red color in a less dense area and the change to a neutral gray in a denser area. A good subject can give very descriptive and reliable

responses which enable one to evaluate the relative densities of different parts of the scotoma.

In searching for scotomatous areas around the point of fixation, one must be careful about labelling an area as nonscotomatous. The two-meter screen will be found very useful for this purpose, since all scotomatous areas are so much larger in their projection on this plane and, therefore, there is less chance of overlooking a defective area. This magnification of defective area is also an advantage in examining a patient who will hesitate to speak up when the test object disappears for only a brief instant as on the smaller screens or campimeters. One should move the test object along the vertical and horizontal meridians—toward the center—rather slowly, so as to give the patient a chance to note a small area in which it disappears. Then, the intermediate meridians (that is, the 45 degree, 135 degree, and so forth) are examined in a similar fashion. I prefer to have the patient keep on saying, "I see it, I see it." In this way, there is less possibility of missing a small patch that may not seem important enough to the patient to report. If the patient just hesitates at one area, that is a lead to explore the area more carefully with weaker stimuli.

When this is over and no scotoma has been found, I like to use "rapid comparisons"—that is, placing the test object in one pericecal quadrant and changing it quickly to another; or, placing it near the point of fixation and then quickly changing it to a point 10 or 15 degrees away in the same meridian. The patient is asked if there is any marked difference in the appearance of the target in these various areas. This method will help to pick up patches of relative scotoma in which the density changes so gradually that the patient will not notice the change with

steady, slow motion. A sudden contrast between this area of relative scotoma and a normal area will make the change more apparent to the patient.

Pericentral quadrants should show up the test target equally well at points equidistant from the fixation point. If the patient says that the target is definitely brighter or clearer peripherally than at a more central point in the same meridian, further investigation should be made, for this information points to some central or paracentral defect.

In describing a scotomatous area as absolute, it is best to use at least a 10-mm., or even 20-mm., white test object on a two-meter screen. Even then, one must remember that this area is absolute for that particular visual angle and may still be only relative for a larger visual angle or with greater illumination.

The use of small white test objects for the study of the blind spot in these cases is often difficult and has its pitfalls. Test objects even as large as 2.0 mm., although normally subtending a visual angle large enough to reach even beyond the 30-degree arc on the two-meter screen, may not reach this far in cases of papilledema or optic neuritis because of the peripheral constriction that often accompanies these conditions. In such cases, the blind spot may fall outside the peripheral field for that visual angle. This same principle holds true for the paracentral area where the isopters for small angles are close to the point of fixation. In other words, in examining the blind spot or the paracentral area, one must be certain that the area investigated falls within the peripheral limits of the field subtended by the particular visual angle used. A simple method for ascertaining this information is to make sure that the patient can see the test object on the screen somewhere temporally to the blind spot. If the field for 2/2,000

white should extend to the 15-degree meridian, thus making this visual angle unsuitable for a study of the blind spot, it is still suitable for evaluation of the pericentral area.

The 1-mm. white test object at two meters must be used with great caution even when exploring the field within the

should wear their corrections. Care should be taken when the patient is wearing bifocals with high reading segments. In such cases, it is best to use a trial frame and trial-case lens with the distance correction only.

CASE REPORTS

Case 1. S. W., a white man, aged 54

Fig. 1 (Chamlin). Case 1. Papillitis with paracentral-field defects. Peripheral-field studies on March 24, 1946, for 5/330 white and 1/330 white. Central-field studies for 10/2,000 white show enlarged blind spots with extension toward, but not quite reaching, point of fixation, and an independent, relative paracentral scotoma in the right eye, with a dense nucleus. White line within the enlarged blind spot denotes the normal blind spot.

5-degree arc. With such small test objects, the carrier becomes very important, and one must be careful to ascertain if the patient is really aware of the white test object rather than of the carrier. I have found the spherical test objects most useful in all my work.

A word or two about wearing of corrective lenses during central field examinations on the two-meter screen seems in order. Young patients with small hyperopic corrections, (+1D. or less) are better tested without their glasses. If the patient's age is more than 35 or 40 years, it is preferable for them to wear even small plus corrections. All myopic patients

years, was admitted to Montefiore Hospital March 21, 1946. A brain tumor was suspected. The patient stated that the vision in his right eye had been a little blurred for the past few days.

Both fundi showed swollen discs with hemorrhages, exudates, and engorged veins. Vision in the right eye was 15/40; in the left eye, 15/20. Field studies done on March 24th revealed a generalized peripheral depression for 5/330 white and an even greater depression with local indentation for 1/330 white. These conditions were more marked in the right eye in which central vision was most affected. Central-field studies were made with

10/2,000 white. Both blind spots were enlarged to almost five times their normal size, with extension of the scotomatous areas toward the point of fixation. There was an independent, relative paracentral scotoma with a dense nucleus in the right eye. In 10 days, the blind spots diminished to less than twice their normal size. In one month, the blind spots were almost

Visual acuity was 15/13 in each eye and remained so throughout a month of observation. The left fundus was normal. The right fundus showed a swollen disc, with hemorrhages, exudates, and engorged veins. Field studies revealed normal findings in the left eye. The right eye showed a localized depression in the lower peripheral field for 4/250 white. The cen-

Fig. 2 (Chamlin). Follow-up of central-field studies on Case 1. Done with 10/2,000 white. A, April 3, 1946; B, April 15, 1946; C, April 24, 1946. Successive studies show diminution in the size of the blind spots, with persistence of paracentral defects.

normal, but the paracentral defects persisted and were still present in August, 1946.

This case illustrates papillitis with little loss of central vision in one eye and practically no loss in the other. Until the central studies were made, the fundoscopic picture and retention of fair central vision led one to believe that the condition was one of papilledema.

Case 2. G. T., a white man, aged 52 years, was seen on May 11, 1946, with a history of a "film" over his right eye for the past week.

tral field for 2.5/1,000 white showed an enlarged blind spot with a relative scotoma extending down from it and spreading and arching around the point of fixation as a Bjerrum scotoma or nerve-fiber-bundle defect.

One month after the original field studies were made, the scotoma showed signs of clearing, but vision remained 15/13.

This case illustrates papillitis with a nerve-fiber-bundle defect and preservation of normal central vision as measured on the Snellen chart. Central field studies gave the necessary proof that this was a case of papillitis and not papilledema.

Fig. 3 (Chamlin). Case 2. Papillitis with nerve-fiber-bundle defect. Peripheral field for 4/250 white shows local depression below, fusing with the relative nerve-fiber-bundle defect coming down from the enlarged blind spot. The central field was mapped out with 2.5/1,000 white.

SUMMARY

The early stages of papilledema and papillitis (optic neuritis) may produce a confusing picture. This is illustrated by the presentation of typical cases. The history, clinical examination, ophthalmoscopic appearance, and visual acuity may

not be enough for differentiation. The study of the central fields of vision is of paramount importance in such cases. However, central field studies present many problems, a few of which are evaluated in this article.

WHICH SQUINTS RESPOND BEST TO ORTHOPTIC TREATMENT*

EDITH ROTH
Chicago, Illinois

The determination of the squints responding best to orthoptic training is one of the most important problems confronting ophthalmologists and orthoptic technicians today. We feel compelled, therefore, to look back on some of our work and search the records for any findings of apparent significance. Every fact which may assist us in making a good prognosis should be brought to attention at this time for several reasons:

1. A correct diagnosis and good prognosis will determine whether the squint is amenable to active orthoptic treatment.

2. Accurate diagnosis makes it easier for the ophthalmologist to place the patient in the proper category and thus put the proper emphasis on the type of treatment to be carried out by the technician.

3. A correct prognosis will make it possible to judge the length of time necessary for treatment, which is an item to be considered when certified orthoptic technicians are so scarce and the demands on their time so great.

4. When the patient can be placed in the proper classification, after a correct diagnosis, the ophthalmologist is better able to determine if and when surgery is necessary. It also aids him in the choice of surgical procedure.

First of all then, let us consider some of the types of squint. It is apparently agreed upon by ophthalmologists and technicians alike that purely accommodative squints offer the best prognosis. The squints which have a large accommodative factor are responsive to orthoptic treatment and refractive correction if the angle of deviation is not over 30 to 50

diopeters, depending upon the accommodative element. Needless to say, the state of fusion must be good.

Squints with a large convergence-insufficiency factor are almost certain to give a good prognosis with a few months of treatment. However, squints with a pure or even a primary divergence-excess factor must be turned back to the surgeon for a truly complete cure. It so happens that most squints show a combination of the two factors, that of convergence insufficiency being the most common.

We have found that the few convergent squints with a larger angle of deviation for distance than for near are often more difficult to train. However, out of seven such cases in the past three years, two have been discharged as cured. We do not believe that any nonaccommodative convergent squints over 25 diopeters are very amenable to cure by orthoptic training alone. Such a course of treatment is only recommended by the doctor when the patient is strongly opposed to surgery and does not consider the time element of treatment important.

Paralytic squints seldom fall into the category of purely orthoptic cases. Some cases of recent paralysis are referred on occasion, but, as a rule, the doctors do not consider even a case of paresis to be receptive to treatment alone. It is certainly true that most cases with a paresis of a vertical muscle must eventually be turned back to the surgeon, as nothing is more difficult for a patient to overcome than the uneven images of a large or highly variable hypertropia. If the vertical deviation is within 6 or 8 diopeters, the incorporation of prisms in the glasses is often adequate until some compensation has been acquired in everyday seeing.

* Read at the meeting of the American Association of Orthoptic Technicians, Chicago, October 14, 1946.

In regard to amblyopic squints, only those patients with 20/50 vision, or better, in the poor eye are considered for active treatment. There does not appear to be any contraindication to a good result when visual acuity has been improved or central fixation has been restored. Preferably, not more than one or two lines difference in visual acuity should be found. The age of the patient is, however, important in considering the improvement of vision or the establishment of central fixation by occlusion or flashing. When the patient has reached teen age, it is difficult to carry through a strenuous procedure such as complete occlusion and monocular homework.

The prognosis of the anisometropic squints is rather difficult to predict. If the anisometropia is not more than 3 diopters and an alternate fixation is established in a short period of time by active treatment and occlusion, it appears to us that there is a possibility of cure. The attempt, therefore, may be worth while. Usually occlusion and treatment must be quite prolonged, even after alternate fixation has been obtained. Our experience with this type of squint has not been adequate to enable us to make any definite statements or positive conclusions. Since it has been noted that a number of cases of anisometropia with suppression or even amblyopia have shown no deviation at any time, it might be that surgery would prove most beneficial.

Most patients with a dissociated vertical divergence appear to have a general nervous instability that in itself is a definite handicap. These cases are said to be neurologic in origin, which makes us feel that the improvement of the patient's general physical condition will, perhaps, be more beneficial than a strenuous orthoptic work-up or possible surgical intervention.

It will probably be inferred from this

discussion of types of squint that there is already some selection of cases at the Milwaukee Ophthalmic Institute. This is true in that a trial series of treatments, consisting of about eight visits, usually weeds out those cases considered uncooperative, not amenable orthoptically, or perhaps not ready for active treatment at the time. Nevertheless, we are only too cognizant of the fact that a greater and better selection of cases is necessary; especially is this so when the element of the time involved in some treatments must be considered. We are only too aware of the fact that we are still groping for added information on many problems.

In approximately three years of work, 255 unselected cases have been studied. Only 146 of these have had any active treatment of any kind. Of this number, 16 have now been discharged as cured, and 53 as definitely improved. Seven patients were discharged by us when several series of treatments failed to give the desired effect, and a score or so of patients have dropped out for various reasons of their own. The remaining number are still on treatment, although some have been given short vacations by the doctor. Frequently, a leave of absence will help to determine a patient's ability to hold what he has gained, and many times it aids one in making a prognosis. Eleven of the 44 cured or improved cases had surgery, five preorthoptically. The length of treatment varied from $2\frac{1}{2}$ months to as long as $2\frac{1}{2}$ years in a few cases. The age of the patients ranged from 3 to 45 years. During the last three years, the lack of personnel has forced the doctors to suggest that we devote the greater part of our time to children, in the belief that by doing this we could accomplish the greatest amount of good. Most of the children have been 3 to 8 years of age.

Our statistics on the findings and results in the treatment of a few types of

squint may be interesting, but you will readily concede that we have gained little of definite value in making a prognosis. We have all ascribed too many failures to certain abnormal physical conditions and too many successes to normal physical reactions. We may also attribute too much importance to the classifications of squint cases and to the statistical findings of such groups. There are certain handicaps to a successful result, we must admit, and these have been stated by too many ophthalmologists and technicians to bear repetition. When we try to sift out certain facts of apparent relevance, however, we realize that there are not sufficient data of statistical importance. Our leads do not *prove* anything; they do not even show much definite correlation. We can only reiterate the claims of others when we state that cases of rather late onset and short duration give the greatest hope of cure without resorting to surgery. As previously stated, our cases of accommodative squints are usually treated without any orthoptic exercises; squints with a large factor of convergence insufficiency can almost certainly be cured with some supervised work and home training; those with a major divergence-excess element require surgery in most instances—that is just about the extent of our findings.

In the final analysis, it is apparently not so much the type of squint which is significant, as it is the type of squinter. One of the most important factors to be considered in the individual case is the fusion status of the patient at the beginning of treatment. Those patients with muscle pareses, mixed correspondence, marked anisometropia, pure divergence excess, or dissociated vertical divergence are all handicapped, but they certainly are not hopeless cases. When only a glimmering of diplopia or true correspondence, a constant alternate suppression, or a persistent, firmly fixed, abnor-

mal correspondence are present, there is reason enough to question the advisability of active treatment. Certainly a trial period of 2 or 3 months with no result in the elicitation of simultaneous macular perception or fusion is sufficient to discourage the most optimistic technician.

On the other hand, patients with quick response to fusion and even a feeble attempt at voluntary control are reasons for encouragement, as they are rare indeed in our Clinic. It has been our experience that a good or poor fusion faculty can only be determined by a short trial period, since there are no positive points in the history of the case to denote this possibility. When onset of the squint is at 3 to 6 years of age with some intermittent appreciation of single binocular vision, we are optimistic. However, a history of squint from birth does not necessarily indicate a poor prognosis. This is especially true if, at some time, the squint was an intermittent one, or if the patient is young (yet coöperative), because the duration of squint is then short.

The exceptions in the cases of squints with poor fusion dating from birth, are too many to enable us to make any positive statements or predictions. There are also many cases with histories of late onset and short duration which prove bitterly disappointing. We do not know how much we can depend upon any history, since so many prove unreliable. Few parents know what caused the squint, whether it is constant or occasional, or whether the onset was sudden or gradual. The squint is usually noted gradually, and, when we make the provisional diagnosis of constant manifest strabismus, most parents tell us the squint is only an occasional one, although it is sufficiently great to be obvious even to the lay person.

In spite of the fact that much is said and written about the poor prognosis of cases with abnormal retinal correspond-

ence, we do not find that most cases with a firmly established anomalous correspondence are much more difficult to treat than those with a persistent marked alternate suppression. Most of our cases show a marked suppression at the start making it necessary for us to treat them for a month sometimes, before coming to a definite decision concerning the prognosis.

Obviously we never diagnose the correspondence until some kind of actual binocular vision has been established; many cases of rapid alternate suppression simulate an abnormal sensorial correspondence, and the patient's answers, even in regard to the crossing of images, are unreliable. The cases of constant monocular esotropia with a rigid and moderate deviation are most likely to show a firmly fixed abnormal correspondence. Most of these cases, as well as most cases of marked alternate suppression, do occur in squints dating from infancy; that is, before three years of age. In fact, 71 out of 92 firmly fixed abnormal correspondence cases, which were studied, were apparently squints since infancy. It might be well to mention here that most of the cases dating from infancy also have a history of an inherited tendency. Out of the 255 cases studied, 109 cases had an hereditary deficiency. Out of the 109 cases giving this history, 86 cases dated from infancy. If the truth were known, inherited fusion deficiency would be a factor in the etiology of many more cases.

Second in importance only to fusion as a prerequisite in successful squint training is the attitude of the patient—the personal desire for cure. At times we feel

this to be the most important consideration in the case, which challenges us all the more. Our experience has taught us that seldom does poor fusion sense, or centers, prove too much of a handicap for the patient who is eagerly intent on improvement—not forgetting, for our part, that at times an apparently insurmountable handicap may discourage the most eager patient. However, we fully realize that, as in any teaching process, the proper stimulus will usually elicit both attention and interest. Our constant questions must be so worded as not to divulge what we may expect or wish as an answer; yet they must help the patient to scan the targets for details that will suggest enough information to elicit further information. In this way the imagination of the patient is stimulated. By constant questioning only are we able to assure sustained attention.

When we survey orthoptics in all its aspects, we must acknowledge that our success or failure depends upon the patient as an individual—as a person to be taught rather than treated. Certainly the patient who is physically and emotionally ready for teaching has the best chance for success. We, as technicians or teachers, must assess the needs of the individual. We must judge the advisability of actively stimulating the patient with a phlegmatic divergent squint by routing his success. We must consider the importance of passively stimulating by subtle suggestions of success a patient with a hyperkinetic convergent squint. It is this personal equation which truly spells success or failure.

203 North Wabash Avenue (1).

DISCUSSION

DR. FRANK D. COSTENBADER (Washington, D.C.): It is a pleasure to discuss Miss Roth's paper. Much has been

written and said on the subject of "Orthoptics" by those who, unfortunately, are not well enough qualified to be help-

ful to us. However, if *we* can correctly state that certain types of squint are helped by orthoptic procedure, and other types are not, we are being helpful. Miss Roth has offered certain thoughts, and, in the main, I agree with them.

In my experience, three groups of cases respond well to orthoptic treatment. The first, convergence insufficiency, while not a squint, is a dysfunction of ocular motility, and rightly should be considered here. Convergence insufficiency is common and makes up the bulk of work in many orthoptic clinics. In my own practice, limited to children, the number is smaller, but these respond quite well to the binocular stimulation of accommodation, which is the chief method of stimulating convergence. We use so-called pencil exercises with many variations, prism exercises, the stereoscope with "base-out" slides, the metronoscope, and the major amblyoscope.

The second group of squints to respond well are the accommodative convergent ones, and, of these, the "typical" respond better than the "atypical." By "typical" I mean those whose esotropia varies directly with the diopters of accommodation being exercised. By "atypical" I mean those squints having a small refractive error, but an excessive esotropia when even moderately accommodating. The dissociation of accommodation and convergence in the typical cases has been most helpful.

By teaching blurred vision with straight eyes, gradual clearing of vision with straight eyes, and the consciousness of diplopia when convergence occurs, hyperopes of 4 diopters or less may learn to stay straight without glasses, and still see adequately. I should guess that 50 percent of typical accommodative esotropes may learn to live happily without glasses for constant wear.

The third and final group benefiting greatly from orthoptic training are the cases of moderate divergence excess. I have the feeling that over one half of the cases having a divergence of 20 diopters or less can be taught to maintain straight eyes at all times except when ill or extremely fatigued. Divergence of more than 20 diopters can rarely be treated by orthoptics alone, but must have one or both lateral rectus muscles recessed, as well.

Orthoptic procedure is most helpful as an adjunct to surgery in obtaining a final cure in the more mechanical types of strabismus. I personally do not emphasize presurgical, but do stress postsurgical, orthoptic training.

May I point out, with Miss Roth, that any degree of success in treating any type of squint requires not only an interested, intelligent patient, but also interested and intelligent parents? Lack of interest will defeat the most sensible and persistent training program.

DIVERGENCE EXCESS: AN ANOMALY OF THE EXTRAPYRAMIDAL SYSTEM*

ELECTRA HEALY

Chicago, Illinois

A review of the literature concerning the condition known as divergence excess revealed the fact that not only are we progressing in our knowledge of this particular condition, but that many of the facts are, and will be, applicable to other types of ocular muscle imbalance as well.

Since there seems to be some variance in definitions given by the different writers on this subject, I should like to make my own understanding of divergence excess clear by quoting from a paper by Berens, Hardy, and Stark, which was read before the American Ophthalmological Society in 1929:

"We characterize as divergence excess that ocular muscle imbalance exhibiting an exophoria more marked when the gaze is directed into distance than when it is adjusted for near vision, combined with normal prism convergence and near point of convergence and an excessive ability to overcome the diplopia caused by prisms placed base in before the eyes. The lateral movements of each eye should be normal and comitant."

The incidence of divergence excess in our office for the past 5-year period—the length of time our orthoptic department has been opened—was approximately 0.8 percent of all eye conditions which required the services of an ophthalmologist, and two percent of all cases which were referred to the orthoptic department. The age of the patient at the time of the first visit varied from 3 to 62 years.

All patients were examined under cycloplegia, with the exception of the old-

est patient. Although cases of hypermetropia predominated in this group, other types of refractive error, including compound and mixed astigmatism, and both hyperopia and myopia, were found. There was also one case of aniseikonia. Therefore, no significant correlation was found to exist between divergence excess and ametropia of any specific type. This is almost in complete accord with the data given by Berens, Hardy, and Stark. I feel that this is of particular interest, because of the lapse of time between the two findings and the different locations in which the studies were made.

One of the oldest theories to account for divergence excess, a theory which I believe I can safely say has been abandoned, was that of "weak muscles." Now this interpretation of weak muscles is not to be confused with the one of poor muscular tone caused by lack of exercise or some constitutional condition such as anemia or ill health, all of which may well contribute to weakened convergence power.

More recently, the theory that divergence is not a negative factor of convergence has been suggested by the possibility of an actual divergence center in the brain. The supposition that overstimulation of such a center is the cause of divergence excess remains unproved, however, to those who have worked with this type of squint. Bielschowsky's opinion that divergence excess is due to an anomalous position of rest, considering the anatomic arrangement of fasciae and ligaments of prime importance, is also unconvincing in the light of what may be obtained by orthoptic treatment.

Just what may be gained by orthoptic

* Read at the meeting of the American Association of Orthoptic Technicians, Chicago, October 14, 1946.

training? Through prolonged, conscientious, and ever-increasing effort in orthoptic training, much may be accomplished. All cases of divergence excess, even the very low percentage of cases requiring surgery, need the additional stimulus that orthoptics can give, more than they need any other one aid in correction. Why is this so? Because orthoptics teach correct habits and skills. If anomalous correspondence is present, it may be corrected by reeducation through fusion stimulation, and by the development of a large amplitude of fusion. The proper relationship between accommodation and convergence may be established and suppression overcome, all because these conditions are established by the cerebral cortex, the center of learning.

Does all of this effect a cure? That depends entirely upon the definition of a "cure." I like to think of a cure as being absolute and habitual at all times and under all circumstances; if that is meant, then the answer is "no." Although these patients may be taught to accomplish the highest standard of "mechanical cure" and transfer it to their "casual seeing," there are still times when deviation is manifest, without the patient's awareness of it, for only rarely is spontaneous cross diplopia noticed by the patient.

This inability, on the patient's part, to know when the eye is divergent—even in view of the satisfactory experience that binocular single vision gives—may be accounted for by the complete absence of any conscious sensation of the position of the eyeball, or even further by the apparent absence of a definite proprioceptive mechanism in the ocular muscles. If this were not so, nerve impulses reaching the central nervous system would give infor-

mation concerning tension of the muscles and relative position of the eye. In sleep, when the cerebral cortex is inhibited, the eyes assume a divergent and upward rotation; but upon awakening, the "fixation reflex" and "attention mechanism," both prompted by the higher level of cortical control, bring them into parallelism. However, relaxation of attention or daydreaming affords opportunity for the unnoticed divergence of the eyes.

Normally, during this period of relaxation, the eyes are held in correct position by synergy or postural tonus. The innervations responsible for these correct positions of the eyeball may resemble those of other muscle systems of the body in being of two types. One consists of conscious perception and volitional direction, as served by the pyramidal tract from the motor cortex; the other, which does not require the attention of consciousness and which effects involuntary adjustment, is subserved by the extrapyramidal system. An anomaly lying somewhere in this little known system accounts for the failure that occurs when the "fixation reflex" or "attention mechanism" is not in complete control.

CONCLUSION

1. Divergence excess occurs in one to two percent of all cases in the private practice of ophthalmology.

2. Divergence excess is not correlated with refraction.

3. Orthoptic treatment is the most satisfactory correction method employed today because it corrects, to a great extent, the neurologic factor.

4. Divergence excess is an anomaly of the extrapyramidal system, and research in this field is urgently needed.

NOTES, CASES, INSTRUMENTS

GLAUCOMA TREATMENT*

P. WEINSTEIN, M.D.

Budapest, Hungary

Since glaucoma is the most frequent cause of loss of sight, its treatment is one of the outstanding problems of ophthalmology and its prevention can be regarded as a national service. Research into the etiology of this disease, study of statistics based on large numbers of cases, rationalization of operative treatment, and analysis of drug therapy are the materials from which ophthalmologists forge the weapons for combatting this disease.

The ophthalmic clinic of Budapest University under the guidance of its late director, Prof. Emil Grosz, undertook extensive work along these lines, and it was the privilege of this writer to take part in the work. The experience gathered from the investigation of several hundred cases during this work and from operations on many patients at the ophthalmic department of the Jewish hospital at Budapest has led not only to the writing of this paper, but also to the observation which is this paper's most noteworthy contribution to the study of glaucoma; namely, that spontaneous venous pulsation signifies a more favorable retinal circulation and that retinal nutrition is less impaired in those patients having spontaneous venous pulsation than in those in whom it is lacking.

Professor Grosz in his last two lectures on glaucoma delivered in 1939 at Nancy and in London (Hunterian lecture) summed up the experience gained from performing 4,927 operations. He outlined instances in which surgery is indicated as follows:

* From the Department of Ophthalmology of the Hospital of the Jewish Community at Budapest.

1. Iridectomy in cases of inflammatory glaucoma.

2. Iridectomy in cases of acute inflammatory glaucoma which react to pilocarpine-lowering of the tension.

3. Posterior sclerotomy followed by cyclodialysis and subsequent iridectomy in cases of acute glaucoma which do not react to pilocarpine.

4. A trephining operation as the first treatment, followed by cyclodialysis, for chronic inflammatory glaucoma.

5. Lagrange's operation followed by cyclodialysis in cases of glaucoma simplex.

Grosz believed that cyclodialysis could be regarded as less dangerous than trephination, but he also recognized that, in trephination, the immediate results, as well as the later effects, are more favorable. The advantage of cyclodialysis, however, is that it can be repeated several times. Insufficient knowledge as to the processes which produce the effects of these operations was, in Grosz's opinion, the contributing factor to the surgeon's inability to make a rational choice.

Experience with many cases in Grosz's clinic demonstrated the fact that posterior sclerotomy in cases which did not respond to pilocarpine during the acute attack resulted in quite transitory decrease of tension; so there was little sense in applying it. Likewise, cyclodialysis contributed little to the lowering of tension during an acute attack. (Goldman says that it is effective only in cases in which the eyes possess deep chambers.)

My experience, based on 346 operations, shows that iridectomy for prodromal and acute glaucoma improved by pilocarpine gave excellent results in 188 cases. In 26 cases which did not respond to pilocarpine during the acute attack and in which the possibility of subsequent

hemorrhage or expulsive hemorrhage excluded iridectomy, I applied Lindner's posterior trephination as a preparatory step and followed this in two or three days with iridectomy. Soon after Lindner's trephination, the tension decreased; the chamber deepened; and the opacity of the aqueous humor, sometimes rich in proteins, disappeared in every case within a few days. By itself, Lindner's trephination is insufficient. In six cases of absolute glaucoma in which posterior sclera trephination was the only treatment, the eye hardened again within six to eight days.

In 53 cases, I applied Heines and later von Sallmann's cyclodialysis. The results were unsatisfactory. Since I had had ample opportunity in Grosz's clinic to follow cases in which the eyes had hardened again after repeated cyclodialysis, I resolved to treat every case of chronic inflammatory and simple glaucoma by Elliot's trephining operation and, to date, I have done so in 57 cases.

The mechanism of the surgical procedures just described have been elucidated by the investigations of Fr. Kiss,¹ professor of anatomy at Budapest University. According to his views, the circulatory system of the ciliary body has been divided into two contradistinctive parts: (1) grossly entwined vessels serving filtration (the ciliary process); (2) thin-walled vessels serving absorption (the ciliary plexus). The beneficial effect of cyclodialysis is due to the liberation of the suprachoroidal space whereby the finely interwoven system of the ciliary plexus becomes free, its circulation accelerates, and absorption increases.

Actual observation confirms that, after cyclodialysis, hyphemia disappears with astonishing rapidity within the chamber, while after iridectomy hyphemia lasts for several days. Kiss's explanation is, there-

fore, plausible enough and a contradiction to other theories (Heine, Elschnig). It is a fact, however, that cyclodialysis is ineffective in 50 percent of cases (Grosz). Obviously, this is so because the formation of synechias obliterate the ciliary plexus, its circulation is impeded and with it, absorption.

Kiss's theory explains that the chamber deepened by Lindner's trephination gives free access to the ciliary body and, thereby, improves conditions for iridectomy. The lasting decrease of tension in Elliot's trephining operation has to be ascribed to filtration and partly to the developing of the vessels (Sondermann) which connect the episcleral veins (anterior ciliary vein) and the ciliary plexus, thereby facilitating drainage.

Since there are cases which, despite iridectomy, repeated cyclodialysis, and Elliot's trephining operation, become hard again and do not react to the 1- to 2-percent pilocarpine solution administered in the conventional manner, I have established a new treatment.² Satisfactory results have been achieved in such cases by administering a combination of 1:1,000 adrenalin, $\frac{1}{2}$ - to 1-percent pilocarpine and, once or twice weekly, 1-percent adrenalin. I have treated numerous cases which remained hard despite operation and the usual pilocarpine treatment and which became permanently soft after this therapy.

During 1944 and 1945, when many glaucoma patients were confined to the ghetto at Budapest and there was no adequate medical treatment nor pilocarpine available, valuable observations could be made.

It was from the detailed examination of these patients and from comparing their fundi with fundi which had been altered by such conditions as high myopia, atrophy of the optic nerve, and so forth,

that we came to the impelling conclusion which is the salient feature of this communication.

Spontaneous venous pulsation signifies a more favorable retinal circulation and where it is present, retinal nutrition is less impaired. Under such circumstances, the increase of blood pressure according to Lauber-Sobansky as a means of general treatment of chronic glaucoma, concomitant with a decrease of venous pressure, may be justified.

SUMMARY

Iridectomy is the operation of choice in cases of prodromal and acute glaucoma responding to pilocarpine by decrease of tension.

Acute glaucoma not amenable to pilocarpine should be treated by Lindner's trephination followed by iridectomy after two or three days.

Elliot's trephining operation is indicated in cases of inflammatory chronic and simple glaucoma.

After-treatment of suitable cases is favorably conducted by the administration of a combination of pilocarpine and adrenalin.

For general treatment, decrease of venous pressure is suitable.

Whatever operative procedure is executed, after-treatment has to be conscientiously followed.

V., Személynök-u. 9-11. 1/23.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

BROOKLYN OPHTHALMOLOGICAL SOCIETY

October 24, 1946

PSEUDOTUMORS OF THE MACULA

DR. RALPH I. LLOYD presented a paper on this subject in which he considered the differential diagnosis of macular disease including consideration of histologic reports as well as clinical history. The vascular degenerative and neoplastic processes were given detailed analysis, their obvious distinctions and often confusing similarities were emphasized. The lecture was supplemented by excellent Kodachrome slides.

OBSERVATIONS ON TRACHOMA WITH SPECIAL REFERENCE TO A "CARRIER STATE"

DR. MARTIN BODIAN spoke on a study of a group of natives working at an American Army Base in Fiji which showed that 22 percent were found to have active trachoma. Of these, 68 percent showed Prowazek-Halberstaedter inclusion bodies on conjunctival smears. Of those natives who were free of trachoma, 34 percent had conjunctival inclusion bodies. These inclusion bodies were found to be identical in every respect to those found among the trachomatous patients. It is felt that this is suggestive of a carrier state in trachoma. American troops living in this endemic trachoma area for long periods of time under hygienic conditions showed no clinical or laboratory evidence of the disease.

INTRAOCULAR FOREIGN BODY UNKNOWN TO PATIENT

DR. CARRERAS presented a case in which the patient not only did not know that he had a foreign body in his eye but denied ever having received an injury to the eye which could have made the presence of a foreign body possible.

The patient had a history of slowly losing the sight of his right eye for a couple of years. He complained that now he had pain in the right eye and some photophobia in his good left eye, which latter fact disturbed him greatly. Examination showed an enormously deformed globe.

The media were normally transparent, but in the cornea could be seen, by means of the slitlamp and corneal microscope, a very thin, peripheral linear cicatrix which comprised the whole thickness of this membrane. The ophthalmoscope showed atrophy of the papilla and a glaucomatous excavation. In the lower-outer section, near the equatorial region of the eye-ground, could be seen a large atrophic plaque of chorioretinitis, of irregular outline and irregularly pigmented. Tension was 50 mm. Hg, and the diagnosis was chronic simple glaucoma, secondary to an intraocular foreign body, in spite of the negative history.

As the patient was anxious to conserve the eye, a cyclodiathermy puncture according to Vogt was attempted. Although the tension fell to 20 mm. Hg, there appeared on the fourth day, in addition to pain, a hyphemia which filled the whole anterior chamber and which showed no

tendency to resorption. In view of this, the eye was enucleated. On examining the enucleated globe, a metallic particle was found imbedded in the choroid, thus confirming the clinical diagnosis.

The rarity of this case is found principally in these two points: (1) The patient was completely unaware of the initial trauma. (2) Secondary glaucoma developed without siderosis bulbi.

Unawareness of the injury which caused the penetration of a foreign body can be satisfactorily explained, if we grant that it might have happened in infancy or that a sterile particle from a work tool penetrated the eye with great velocity causing only slight pain and slight redness of no importance.

The manifestation of a foreign body in the form of glaucoma without siderosis is something of great rarity in ophthalmic literature. The pathogenesis raises many difficulties. We may say it is a case of glaucoma through retention or through deficiency of drainage due to the obstruction of the trabecular tissues of the pectinate ligament by the oxidation products of the iron.

Discussion. Dr. Marin Amat congratulated Dr. Carreras on the study of the chemical analysis of the ocular contents of the patient and suggested that the histopathologic analysis of the retina would have been as interesting as it was in a case of his own which he presented, in 1934, to the Ophthalmological Society of France. In that case, with a dye of ammoniated silver, he showed in the retina the presence of many microglial cells, microphotos of which were published in the *Bulletin* of the Society and in the *Annales D'Oculistique* of Paris with the original work.

Dr. Mario-Esteban. The case presented by Dr. Carreras is very instructive not only because of the long presence of an intraocular foreign body, unknown to the

patient, but principally because of the histopathologic reactions and the biochemical reactions which such a tiny particle could arouse to produce glaucoma.

Dr. Carreras (in closing), replied to Dr. Martin Amat. No anatomic examination of the eye was made because it would not have taught us anything, which is what one seeks in the study of the things gained by surgery. We all know that our ignorance of the pathogenesis of primary glaucoma is due, above all, to the difficulty of obtaining glaucomatous eyes in the first stages of the disease, in order to study them from the viewpoint of the first changes. Old glaucomatous eyes show us lesions which are the result of the disease and not the cause of it. This is a case of absolute glaucoma, of at least two years' duration, and a study of the changes found in this eye would have taught us nothing new.

In his reply to Dr. Mario-Esteban Dr. Carreras thanked him for participating in the discussion of the case presented, and said that his remarks were always interesting and carried the value of his large and rich experience. Dr. Carreras said that during our war of liberation there were many foreign intraocular bodies unknown to those who had them. He could attest to that since he was chief of the ophthalmological service of the six hospitals in Cadiz. However, what is frequent and natural in war where in the excitement of combat a soldier may be unaware of the trauma caused by a projectile is quite a different matter in times of peace where one generally takes note of the slightest injuries save in exceptional instances as seems to be the case in our patient.

A PARTICLE OF IRON IN THE VITREOUS REMOVED BY THE SCLERAL ROUTE

DR. MARIN AMAT AND DR. GARCIA MANSILLA presented a patient from

whose eye a foreign body was extracted within 18 hours after its penetration. The following technique was used.

Retrobulbar anesthesia was performed with 2 cc. of 4-percent novocain to which a drop of adrenalin (1:1,000) had been added. An injection of 2 cc. of 2-percent novocain with two drops of adrenalin (1:1,000) was made in the lower-outer quadrant of Tenon's capsule beneath the external rectus and the inferior rectus muscles. Superficial anesthesia was obtained with 4-percent cocaine.

1. A nonmagnetic eye speculum was placed and an incision was made in the conjunctiva and Tenon's capsule in the lower-outer quadrant along the 4:30-o'clock meridian, exposing a large section of the sclera.

2. A silk thread was placed under the external and the inferior rectus, and these muscles were drawn upward and inward so as to expose the sclera.

3. The large cone of the giant electro-magnet was applied to the sclera in order to attract the foreign body.

4. Diathermy coagulation of the antero-posterior surface of the sclera was done in the same meridian to avoid hemorrhage of the choroid.

5. Three interrupted and equidistant sutures were placed between the lips of the conjunctival wound in order to tie them immediately after extraction of the foreign body so as to avoid loss of vitreous.

6. An anteroposterior incision of some 5 mm. was made with a Graefe knife along the line of coagulation in the sclera embracing this membrane and the choroid. This was done without the least hemorrhage.

7. The long, thin part of the electro-magnet was introduced into the vitreous, and by using the proper current and leaving it in for several moments, the foreign body was extracted. This proved to be a

piece of steel of the form shown in the X-ray film. There was no loss of vitreous.

8. The sutures, already prepared in the bulbar conjunctiva, were tied. At the end of the operation a drop of sterile 1-percent atropine and 4-percent mercuriochrome were instilled in the eye and a monocular bandage was applied.

As a preventive measure, the usual dose of cibazol, internally, injections of cephone, and later calcium chloride, orally, were prescribed. The postoperative course was uneventful. There were no hemorrhages and only a very slight oozing of vitreous during the first three days, which afterwards completely disappeared. On the fourth day vision was 6/6. The conjunctival sutures were removed on the 10th day, and by the 14th day of the accident, there was a complete cure with 6/6 vision in both eyes and no incapacity.

Discussion. Dr. Mario-Esteban agreed with Drs. Marin Amat and Mansilla that the scleral route is the best for extracting foreign bodies located in the posterior segment of the eye. It is a more efficient and harmless procedure than the anterior route. I presented a similar case last year before this society to emphasize this point.

I think it is a wise procedure to produce superficial electrocoagulation as a prior step to sclerotomy, not only in order to prevent hemorrhage but also to avoid a secondary detachment of the retina. To this end it may also be advisable to cut the ocular membranes with an electric bistoury instead of with a knife.

Dr. Marin Amat (in closing), said that he wished to answer, at the same time, Drs. Mario Estaban and Carreras, and to affirm that he considered his technique of coagulation of the sclerotic and choroid and incision with the Graefe knife superior to their method of cutting the membranes with the electric knife. His reason is that the diathermy coagulation produces a better coagulation than is pro-

duced by perforation with a metallic filament. He feels so strongly about this point that every time he has to perforate the eye in the treatment of retinal detachment in order to let the subretinal fluid escape, he always does it over a region which has previously been coagulated so that there will be no complication of intra-ocular hemorrhages.

With reference to the probable subsequent detachment of the retina, it is clear that it could happen, but Dr. Marin Amat has never seen it. The preceding coagulation of the sclera and choroid would produce an exudative choroiditis. This would logically prevent such an occurrence by producing an adhesion of the two intraocular membranes along the site of the incision. Moreover, he performs posterior sclerotomy in the iridectomy operation for glaucoma, without getting subsequent detachment of the retina.

PETER C. KRONFELD, *president*

CLINICAL MEETING

(Presented by the staff of Loyola University Medical School, Department of Ophthalmology)

MALIGNANT EXOPHTHALMOS

DR. J. R. FITZGERALD presented I. M., a woman, aged 47 years, who was seen in consultation in November, 1944, when she was admitted to the hospital for thyroid surgery. The ocular symptoms consisted of lid swelling, epiphora, and a severe and constant neuralgic pain located behind the eyes. A firm, noninflammatory lid edema

was present, as were a nonobstructive and marked epiphora, and a marked retraction of the levator, but no significant exophthalmos. Other ocular findings were normal. Basal-metabolism rate was +39. Following complete ablation of the left lobe and removal of about 90 percent of the tissue of the right lobe of the thyroid, the systemic manifestations of thyroid overactivity disappeared, but the eye symptoms were not improved.

About one month following surgery it was quite evident that malignant exophthalmos was developing. Exophthalmos measured 25 mm. (Luedde) in each eye, and there was considerable resistance on attempts to compress the eyeballs into the orbit. Lid swelling and epiphora were much more apparent; the lacrimal gland was papable; diplopia was constantly present with complete immobility on attempts to rotate the eyes into the superior plane. The diplopia could be obliterated in the primary position by 6 diopters of vertical prisms. The ocular muscles could be palpated and seemed enlarged and taut. Reaction to prostigmine was negative. Vision was: O.D., 20/200, correctible to 20/20; O.S., 20/100, correctible to 20/25. The refractive error was a mild, compound myopic astigmatism. Visual fields were normal.

Six weeks following surgery the ocular situation had further deteriorated. There was almost complete external ophthalmoplegia, inferior rotation being retained to some extent. Severe chemosis was present with exposure keratitis manifest by superficial, punctate staining of the lower half of each cornea. The basal-metabolism rate was -7. The patient was again hospitalized and given 6 gr. of thyroid extract, daily; stilbestrol, 10 mg. daily; fluid limitation; sedation; local protective ocular therapy; and irradiation of the pituitary gland. X-ray studies of the sella turcica were negative. The re-

sponse within one week was excellent. During the next few weeks, the ocular motility improved markedly with lessening of diplopia and subsidence of pain. Seven months following surgery, the diplopia had disappeared subjectively; approximately 1.5 degrees of vertical imbalance remained. The exophthalmos still measured 24 to 25 mm. (Luedde). Rather complete paralysis of elevation remained; left lateral conjugate rotation was also slightly impaired. Cosmetically, the levator retraction is still a problem and a recession by the Goldstein technique is contemplated.

SIDEROSIS OF LENS AND VITREOUS

DR. J. R. FITZGERALD presented E. L., a man, aged 34 years, first seen in December, 1945, because of impaired vision in the right eye of 10 years' duration. He had been told, in 1936, that he had a congenital cataract. Vision was: O.D., 20/60, correctible to 20/30, no Jaeger; O.S., 20/15, J1 for near. In the right eye, a 2 to 3 mm., through and through, linear and vertical corneal scar was seen, located paracentrally at the 2:30-o'clock position, opposite the pupillary margin of the iris. A peculiar lens opacity, consisting of a dense brownish opacity surrounded by a cuff of whitish tissue, was located at the superior pole of the lens in the cortical zone, from which, extending downward toward the lenticular center, were two similarly colored pronglike opacities resembling the roots of a tooth, located in the anterior and posterior cortical zones. The posterior subcapsular zone was greenish-yellow.

Vitreous strands were thickened and clumped, nasally and below, and stained deep brown. A red reflex was present, but fundus details were too indistinct to be studied. Repeated tonometric examinations were within normal range. There was no evidence of active or

past inflammatory reaction; no atrophic changes were present in the iris; and no hole was visible. On maximal pupillary dilation, a small capsular rent was visible just inferior to the equator slightly nasally to the 12-o'clock position. X-ray pictures showed a small, metallic foreign body located somewhere in the anterior orbit or eyeball.

Additional history disclosed that, in 1932, while repairing a battery, something struck the patient's right eye. He consulted a doctor but nothing was found, and the eye healed without incident. In 1942, he was inducted into the army and was promptly hospitalized because of troublesome headaches. He spent four months in the hospital. Numerous X-ray studies were made. He believed that an intraocular foreign body was suspected, but no diagnosis, advice, or therapy was given.

CATARACTA COMPLICATA: MYOPIA

DR. E. A. ROLING presented S. C., a woman, aged 50 years, who was first seen in November, 1942, complaining of poor vision in both eyes. She stated that at five years of age she was struck in the right eye with a pellet from a slingshot, causing loss of vision. She was told at the time that she had a retinal detachment; no therapy was instituted. Vision has remained poor in that eye, and for the past several years vision in the left eye had gradually decreased. She had worn a correction for myopia for 20 years.

Vision in the right eye was ability to count fingers at six inches; in the left eye, 20/100. The right eye showed a mature cataract suggestive of cataracta complicata. There was good projection and perception of colored light, with a faint red reflex at the periphery of the lens. The left eye also showed an opacity of the lens, suggestive of a cataracta complicata, not so marked as in the right. The vitre-

ous was degenerative, the fundus showed degenerative myopic choroiditis.

One year later vision in the right eye was unchanged; that of the left eye had decreased to less than 20/200. A lens extraction was performed in the right eye. The postoperative course was slow but uncomplicated. Three months later vision could be corrected to 20/40; and one month later, with correction: -50D. cyl. ax. 90°, a vision of 20/25 was obtained; with a +3.00D. sph. added, she read J2 at 12 inches. Funduscopy examination showed moderate vitreous degeneration and degenerative myopic choroiditis, less in degree to that of the left eye.

RETROBULBAR ABSCESS

DR. E. A. ROLING presented P. A., a man, aged 50 years, who was first seen in September, 1945, with marked proptosis of the left eye. The lids were edematous and inflamed, and thick rolls of phlegmonous conjunctiva extruded through the palpebral opening. The bulb was completely frozen in the swollen soft tissues of the orbit. The cornea was exposed over the lower two thirds and was hazy. The media was cloudy, and fundus details could not be made out. Vision in the right eye was 20/40; in the left eye, nil. The patient's temperature was 102.4°F.

Three days following extraction of a tooth, two weeks previously, the left eye became red and painful. The eye was treated with hot applications, and sulfonamides were administered without improvement. Ten days after onset, the patient consulted an ophthalmologist and was immediately admitted to the hospital.

Under sodium-pentothal anesthesia, an aspiration of pus was attempted in order to localize any pocket of purulent material in the retrobulbar space. This was unsuccessful, and an incision was made through the skin at a junction between the inner one third and outer two thirds

of the orbit, just inferior to the superior orbital rim. Exploration was continued with blunt dissection until an abscess was encountered. A rubber drain was inserted deep in the retrobulbar space and the wound was left open. Therapy with penicillin and sulfadiazine in large doses was instituted. The wound drained freely; the temperature dropped; and the inflammation gradually resolved. At no time was there evidence of meningeal irritation. Vision in the right eye returned to 20/25, and the left eye remained blind. Two months later, there was only slight impairment of the ocular motility and beginning optic atrophy in the left eye. At present the ocular motility is normal, the optic nerve is atrophied, and there is a slight symblepharon of the lower lid.

SCIENTIFIC PROGRAM

Complications of intracapsular extraction. Dr. Samuel J. Meyer.

Peripheral vision and experimental anoxia. Dr. Ward C. Halstead (by invitation).

Subdural hematomas in infants and adults. Dr. Frank W. Walsh (by invitation).

Richard C. Gamble,
Secretary.

DR. HOWARD F. HILL, *presiding*

PENICILLIN IN OPHTHALMOLOGY

DR. EDWIN B. DUNPHY said that penicillin is usually superior to the sulfonamides for the following reasons:

1. It is generally nontoxic by all routes of administration.
2. Its antibacterial action is not in-

hibited by autolytic products and secretions.

3. It has little, if any, deleterious effects on the regeneration of corneal epithelium.

4. It is not incompatible with other drugs commonly used, such as atropine, cocaine, procaine, sulfadiazine, and so forth.

With these advantages, Dr. Dunphy said, it should be the drug of choice in treating any ocular infection known to be due to penicillin-sensitive organisms.

However, unless certain basic facts are understood regarding its distribution in the ocular tissues by various methods of administration, many cases will not be treated effectively, and much valuable time will be lost before the ocular infection can be brought under control.

The weight of experimental evidence seems to indicate the following recommendations for treating eyes infected with penicillin-sensitive organisms.

1. Intramuscular and intravenous injections of penicillin will probably have little effect in controlling infections of the anterior and vitreous chambers.

2. Subconjunctival injections may have some effect on infections of the anterior chamber, but are probably worthless in infections of the vitreous.

3. Injections of the vitreous can probably be most effectively treated by a single intravitreal injection of 0.1 cc. of penicillin solution containing not more than 500 units.

4. Infections of the anterior chamber will probably be controlled by local application of saturated cotton packs, or by iontophoresis. Corneal baths and subconjunctival injections will probably be less effective. In cases of perforating corneal injury with damage to the lens, a single injection of 0.1 cc. of a solution of penicillin containing not more than 500 units may be justified.

5. For conjunctivitis and infectious corneal ulcers, frequent instillations of penicillin drops or ointment will probably be effective. Saturated cotton packs under the lids, iontophoresis, or corneal baths should be tried in very severe cases.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois; Society Proceedings to Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Alhnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

ESTABLISHMENT OF AN AMERICAN BOARD OF OPTICIANRY

One of the most vital elements in the practice of many ophthalmologists is the opticians to whom they refer their patients for the filling of their prescriptions.

There are those ophthalmologists who are so situated that they cannot allocate this phase of their practice to an op-

tician and who must, therefore, handle it themselves, and there are a few to whom the service is available but who do not care to use it, for one reason or another, but for those who have been fortunate enough to have had an association with a well-trained optician, there can never be enough said in praise of this helpmate.

How often has he borne the brunt of complaints for unsatisfactory glasses, and often, I am sure, when the blame should have been placed elsewhere! How

often has he made requested adjustments and changed lenses without charge to the patient in order to be of service to the physician. His must often be a trying and difficult task. At times, because of his better knowledge, perhaps, of newer designs in frames and bifocal segments, and even—be it hesitantly suggested—better information on practical optics, on him falls the burden of suggesting tactfully to the doctor that certain changes be made in the construction of the lenses.

There are some opticians, naturally, who are not so well trained, even if equally well intentioned, as others, and it is because of this fact that the idea for some means of educational standardization for opticians was born. It is recognized that many good opticians have risen from the ranks of errand and bench boys in the shops, having been trained only by the method of practical instruction and such reading as they cared to do on the subject. Although some of them have made a good job of it, the fact remains that many are inadequately trained and that there is an enormous difference in their qualifications.

Today the demand for more thoroughly trained opticians is even more pressing than in the past because of the great advances in lens construction with the incident increase in variety of optical possibility offered to the public. To be conversant with what is best for the patient involves a knowledge of optics, of lens making, and of many kindred subjects including a reasonable understanding of ophthalmology.

An ophthalmologist who has had particular awareness of the need for better instruction for opticians has been Dr. William L. Benedict, Director of the Ophthalmological Division of The Mayo Clinic. Primarily through his efforts, there has been initiated in the Rochester Junior College a two-year course in Op-

ticianry, a term coined by Dr. Benedict. The theoretical instruction is given under the auspices of the school and the practical work by officers in the Benson Optical Company.

With full realization of the need for some means of evaluating the education of opticians and of standardizing their training, a group of those interested met in Chicago in January of this year and undertook the organization of an American Board of Opticianry. The model was that of the American boards of various specialties in which the American Board of Ophthalmology was the pioneer. The following organizations were instrumental in formulating the idea, and their representatives were included in the plans for the Board:

1. American Society of Contact Lens Technicians.
2. Association of Independent Optical Wholesalers.
3. Guild of Prescription Opticians of America.
4. Optical Wholesalers National Association.

Among the guests was William L. Benedict, M.D., who, by invitation, read a paper on "Recommendations for Creating a Board of Registration for Opticians." Charles Sheard, Ph.D., then emphasized the importance and necessity of adequate education to be followed by an apprenticeship of several years with final examination and certification by the Board of Opticianry as "Master Ophthalmic Optician."

There was to be an advisory educational and professional council to "... consist of not less than three and not more than five members, one of whom shall be engaged in the practice of ophthalmology, one engaged in the practice of optometry, and one who shall be an educator and/or research worker in ophthalmological optics or in the broader

field of physiological optics. . . ."

An outline of a two-year course of training has been sketched. This is to be followed by at least a five-year apprenticeship before the candidate is permitted to apply for certification as Master Ophthalmic Optician. A list of those companies, groups of individuals, or individuals who have been accredited as satisfactory for giving the practical training is to be published.

This training is specified to consist of not less than one year of ophthalmic lens grinding with 40 hours per week, two years of ophthalmic lens finishing with 40 hours per week, and two years of ophthalmic dispensing with 40 hours per week.

The two ideas, one for the establishment of suitable schools for training in opticianry and the other for the formation of a Board of Opticianry, appear fundamentally sound. There is little on which to build at present so that the project will take a long time before it can function adequately. With courage and persistence and infinite patience, however, the purpose can undoubtedly be accomplished. Ophthalmologists and optometrists should give the idea wholehearted support. The former for reasons obvious to ophthalmologists, and the latter for the same reasons—although these are less obvious to ophthalmologists because many of them fail to realize that the practice of many optometrists in large centers is similar to their own in that some of them refer their optical work to opticians. Somewhat beside the point is the related thought that if and when optometrists make a charge to the patient for their professional services, as a very limited number now do, they will not need to depend for their living on profit from the sale of glasses or on rebates from opticians, as is often the case now; and this latter practice might, with ophthalmolo-

gists' coöperation, be stopped and the cost of glasses to the public be reduced.

Having digressed thus far, the writer cannot resist the temptation to reaffirm his often given views on the practice of ophthalmology as concerns refraction. The occasion is because among the excellent papers presented at the organization meeting of the American Board of Opticianry, one writer voiced the sentiment, so often heard from optometrists, that the logical ultimate division of fields of activities might well yield all refraction to optometrists. To this writer that would be the knell of ophthalmology as a specialty.

Half of an ophthalmologist's life is over by the time he has completed his professional training. Ten years more must elapse before his surgical practice amounts to much, even when he is most favorably situated. It is rare indeed for surgery to be his major source of income before he is 50 years of age, and there are many to whom this never occurs. The medical phase of his practice comes earlier. In the practice of most ophthalmologists, however, the medical and surgical parts are always secondary to the refractive portion.

If this is taken from them, only very large cities will be able to support an ophthalmologist. Even there, he would have so many lean years that the field would attract almost no one, and the specialty would have to be included with general surgery where it would languish and deteriorate, a step backward of a hundred years.

Furthermore, refraction of the patient completes the surgical or medical care of the case. It is so intimate a part of the patient's care that it cannot be satisfactorily divorced from it. Since it rounds out the whole treatment and is the logical termination of the case, it should be handled by the one who has

performed the surgery or given the medical care.

No, if there is ever to be general accord between ophthalmologists and optometrists, it must be on the basis of acknowledgment by both that the practice of refraction belongs naturally and legitimately to both.

Lawrence T. Post.

SENSITIVITY FROM TOPICAL USE OF SULFONAMIDES AND PENICILLIN: A WARNING

Recently, while combing the literature for newer developments in the field of ocular therapeutics, I was struck by the widespread, and at times indiscriminate, use of the sulfonamides and penicillin. These miracle-working drugs have a definite and important place in our therapeutic armament, but the indications for their use are now rather well defined and well understood. From the literature it seemed apparent that many ophthalmologists are unaware of the fact that the local use of these drugs, particularly the needlessly long use, may produce a sensitivity to the drugs that would prevent their life-saving use for a later, more serious general infection.

Induced sensitivity from topical use of the sulfonamides is well known to all dermatologists. The reaction consists of a dermatitis of varying severity. In the majority of cases the reactions followed the local use of the drugs in ointment form. It has been found that the local use of sulfathiazole in even infinitesimal doses can induce this sensitivity.

All of us are aware of the fact that ophthalmic ointments can cause a local reaction. This sensitivity is sufficient to produce a severe reaction if the drug is used systemically. In addition to the se-

vere exfoliative dermatitis, the function of the kidneys may be affected, producing anuria, and the blood may show the well-known changes in its structure.

It has been said that, if an individual develops a sensitivity to one of the sulfonamides, another member of the group can be used without danger. There are, however, a number of instances in the literature where individuals who have been sensitized to one member of the group by means of local use have developed a severe dermatitis after the oral administration of another type of sulfonamide. Many internists are very reluctant to give any form of sulfonamide if the patient has ever had a skin reaction to any of the group. Indications are that this sensitivity may last many months and perhaps years.

Experience has shown that the local use of the sulfonamides in the eye is less apt to produce sensitivity than their use on the skin. The use of the sulfonamides in otolaryngology has confirmed the fact that their local use on the mucous membranes can produce sensitivity. There is a striking case reported in the literature of a man who used nose drops containing one of the sulfonamides. Later he developed a pneumonia for which he was given a sulfonamide. A severe exfoliative dermatitis and anuria followed, resulting in his death. There have been a number of authors who have condemned the routine use of the drug in the treatment of the common cold.

Although the generalized use of penicillin is more recent, it is also apparent that there is a tendency to develop a sensitivity to this drug. This sensitivity may be manifested as an immediate reaction or as a delayed one. The delayed or acquired sensitivity may be produced by repeated local application. Reactions have also been seen in the skin and eyelids of individuals who are in contact with the

drug during its preparation for administration. Tests have shown that this acquired sensitivity may be of short duration or it may last for a considerable period, even months, and it is conceivable that it may be permanent.

From the literature it is apparent that the serious ocular infections that respond to the sulfonamides and penicillin do so in a relatively short time. For example, in almost all of the reports on ophthalmia neonatorum the authors stressed the fact that the condition cleared in 24 to 48 hours in most cases and that all were cured before six days. In spite of this knowledge, it is customary in some quarters to use these drugs over a long period of time without regard of the possibility that the patient may be developing a sensitivity.

A personal discussion with Thygeson on this subject brought out some points that it seems well to emphasize: (1) Sulfadiazine is just as effective in the eye as other forms of the sulfonamides, is less toxic, and is less apt to produce sensitivity. (2) The sulfonamides should not be used longer than two months. (3) Unless there is some definite indication for penicillin, it should not be used; it is important to avoid the development of a sensitivity that would prevent its use in a more serious condition. (4) If penicillin is employed, it should be used at frequent intervals and should not be used locally longer than two weeks.

As ophthalmologists let us not jeopardize our patient's future by producing a sensitivity to these drugs as the result of their injudicious use for some rather trivial eye condition or as the result of their needless use over too long a period of time. It must be kept in mind that the sensitivity induced may mean the inability to use these life-saving drugs in later years when they alone can preserve life.

Frederick C. Cordes.

BOOK REVIEWS

MEDICINE IN THE CHANGING ORDER. Report of the New York Academy of Medicine, Committee on Medicine and the Changing Order. The Commonwealth Fund, 1947. 232 pages. Price, \$2.00.

The New York Academy of Medicine organized a committee about four years ago for the study of modern trends in medicine. In this book the subject is fully discussed. The work was based on many original monographs about related subjects. The committee was composed of more than 50 distinguished doctors, nurses, and laymen. The product of their efforts is worthy of the group. The scope of the inquiry is tremendous and obviously a Herculean effort has been put into this book. In the reviewer's mind it is the most thoughtful publication thus far concerning the future of medicine in America and should be read by every physician because it concerns him most intimately.

After a preamble which discusses the origins of the present problems, reviews medical care as it has developed in America and also considers some of the reasons for the trends that it has followed, the status of medical care in rural and in urban areas is given.

A summary of recommendations on the extension of medical care in urban communities is divided into the needs of: (1) middle-income families, (2) the medically indigent; and (3) the indigent. The statement is made that for the middle-income families voluntary, nonprofit insurance plans should be provided and that these can best function through group-practice units. As complete coverage as possible, except for the hospitalization of chronic illnesses, should be provided. If necessary, government funds should be used to subsidize the

risks of establishment and early deficits. The medically indigent should be handled by prepayment, nonprofit insurance plans in which the patient pays only a part of the premium, the rest being met by local, state, or federal funds. The indigent should be cared for by improved facilities in tax-supported municipal hospitals and health centers, with municipal subsidies to improve nonprofit institutions and staffs. A panel of physicians should give office and home care to these people. A medical committee should be set up in each city for advising the municipal agency that extends government subsidies to health institutions and to nonprofit insurance plans.

Situations in rural districts, which are much worse than in urban areas, are to be met primarily by an expansion of federal, state, and local public-health services. Qualified doctors, whose salaries are augmented by municipal, federal, or state grants, should be employed. Mobile clinics are recommended and, as the heart of the undertaking, new hospitals and health centers are to be strategically distributed throughout the country. Here again federal funds are to be utilized, the amounts depending on the local situation.

The next chapter considers the extension of the aforementioned public-health services which are now fairly adequate in some few states, only partially adequate in some others, and completely inadequate in the remainder. A recommendation is made that the federal administration consolidate all health functions in the Public Health Service and that this should eventually be elevated to departmental status. A consolidation of state health activities is badly needed. Too many departments, such as Welfare, Labor, and Agriculture, are involved in the present arrangements.

The quality of medical care, as distinct from the quantity, is stressed, it being recognized that the two are not necessarily interdependent and that if the quality deteriorates, the increase of quantitative care is futile.

Education of medical students, particularly the abandonment of discrimination against women and minority groups, is discussed together with the present economic discrimination. Pertinent suggestions are that preventive medicine should be employed to a greater extent than at present. Each case should be studied with the thought in mind as to why the condition was not forestalled. It is also suggested that the student should have more instruction in medical practice in the home than he now does. Economics point to the impossibility of giving good medical education at a price that the student can pay. Government aid seems the answer to the writers of this book.

Another thought is that clinical training should begin with the first year of medical school, and that the basic courses should not be given in an isolated manner but directly in relation to the care of the patient. For the best training of interns they should be under the supervision of the medical school. Too often an intern is merely an employee of a hospital and carries such a mechanical burden that he does not have time to advance intellectually. It is argued that medical schools should have some contacts with their graduates' training. The idea is advanced that possibly medical schools, presumably accepted ones, might well have the licensing power of the physicians whom they have taught. Then follows a discussion of group practice. To the writers this seems to be a most desirable development.

A chapter on preventive medicine

points out as a preliminary that preventive medicine applies to those practices which only the individual is capable of applying to his own benefit; whereas, public health is a community responsibility. Prevention is tremendously stressed. The physician should be prepared to advise the patient not only on how to get well, but on how to keep well, and every individual should be educated to the importance of demanding this information from his doctor.

The history of the development of hospitals in America is a fascinating chapter. It discusses many aspects, not the least important being the financial, which includes the increasing costs to patients of hospital care. The necessity of this in the overall expanded program is, however, obvious. This chapter concludes with 22 recommendations for more efficient hospitals. Among these, the most important are a further integration of in-patient and out-patient services, with the enlargement of the latter and the extending of the hours of service into the evenings. The need for more graduate practical nurses is given. In this instance, as in others, the unequal distribution of service is mentioned. In New York state, the ratio of graduate nurses to population, in 1943, is given as 1:620; while in Mississippi, it was only 1:4,958. Although many more trained nurses are needed, the urgency for practical nurses is, perhaps, even greater.

Perhaps the crux of the whole problem is contained in the discussion of medical insurance. The committee strongly urges an extension of the voluntary insurance plans, which have been tried in many states and which, in general, have proved successful, rather than the establishment of drastic and irrevocable compulsory, health-insurance schemes, such as those

outlined in the Wagner-Murray-Dingell bill, which have no experience to back them.

A glance at the italicized paragraph headings of this culminating chapter, gives one a fair idea of the whole discussion. "In extending medical service and perfecting its organization, quality must be preserved. Provision of public health services is a prime essential. Improvement in medical service requires effective use of hospitals with adequate facilities. Success will require trained professional and nonprofessional personnel. For optimal results, organization and coöperation of physicians are required. In the improvement of medical services, voluntary prepayment plans are needed. Extensive education for both physicians and the public will be required. Progress in the extension of medical service must be varied and adapted in each instance to the needs of the community. Government aid will be required."

Lawrence T. Post.

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM. Volume LXV. London, J. and A. Churchill, Ltd., 1945. 424 pages.

The abundance of medical and surgical material cast off by war has always been followed by advances in medical knowledge and surgical skill. The excellent "Discussion on the Ocular Sequelae of Head Injuries" and the "Discussion on Plastic Repair of the Lids" carry the weight of authority gained from actual experience. The ocular sequelae of head injuries are presented in the following order: (1) optic nerve, (2) optic chiasma, (3) optic tract and radiations, (4) visual cortex, (5) visual disorientations,

(6) neuromuscular aspects, (7) the visual fields, and (8) the orthoptic treatment of ocular muscle imbalance following head injuries. This is controversial. The psychological benefit is noted frequently.

"The technique of plastic surgery is like that of eye surgery. Every maneuver must be precise, purposeful, clean, and finished. The handling of tissue must be the minimum." This quotation from Stallard's article is repeatedly confirmed by the very fine case reports and photographs presented. The lessons of World War I which have been so thoroughly taught by John Martin Wheeler have been verified again in the field of plastic surgery.

The Doyné Lecture, "On Compression and Invasion of the Optic Nerves and Chiasma by Neighboring Gliomas," is of considerable historic interest in revealing the development and recognition of the syndrome which was first presented in an extended form by Foster Kennedy.

Many individual case reports are scattered through the transactions.

William M. James.

CORRESPONDENCE

GLAUCOMA FOLLOWING INGESTION OF SULFATHIAZOLE

Editor,

American Journal of Ophthalmology:

In the February, 1947, issue of the JOURNAL is an article by Fritz and Kesert reporting a case of glaucoma caused by sulfathiazole. The diagnosis of acute congestive glaucoma in the case reported is seriously questioned on the following counts:

1. The vision of either eye was corrected to normal by glasses.

2. The pupils were small and irregular.

3. The fundus was recorded as normal through undilated pupils.

4. The pupils, three days after the original acute attack, were normal in size and reacted briskly to light and accommodation despite the fact that eserine was being used in both eyes.

There is no doubt, from the case reported, that the patient was allergic to sulfathiazole. The edema of the lids and the chemosis, plus the intense itching and burning, were indicative of an allergic reaction. The incidental increase in pressure is not to be regarded as acute congestive glaucoma because the pupils were not dilated, the fundus could be seen, and the visual acuity was normal with glasses.

I think the authors have made a mistake. All acute inflammatory diseases bringing about edema and chemosis may be attended by increased pressure of the eyeball by purely a mechanical process. Acute iritis and acute anterior uveitis may be attended by increased intraocular pressure. These experiences which register a higher than normal tension on the tonometer are not to be regarded as acute congestive glaucoma.

(Signed) Louis Lehrfeld,
Philadelphia, Pennsylvania.

Editor,

American Journal of Ophthalmology:

Because of the difficulty in arranging a conference with Dr. Kesert, I will undertake to answer Dr. Lehrfeld's letter, assuming full responsibility therefore and not presuming, of course, to speak for Dr. Kesert, who might not subscribe fully to what I write.

Dr. Lehrfeld thinks that we were mistaken in our diagnosis. Indeed it is pos-

sible that we were. However, two well-known ophthalmologists, editors of the JOURNAL, saw the patient with us and agreed with the diagnosis and treatment.

Dr. Lehrfeld agrees that this attack of ocular disease was an allergic phenomenon. It certainly was acute. The turgid condition of the ciliary and conjunctival vessels made it appear congestive, and the increased tension relieved by eserine meant glaucoma as we are accustomed to think of the condition. We were struck by the good visual acuity, the small irregular pupils, and the clear corneas, but, because these findings were at variance with the classical picture of acute congestive glaucoma, we did not feel that the diagnosis was in doubt.

In classic, acute, congestive glaucoma, when promptly and successfully treated, a normal fundus has been recorded frequently. The pupillary reaction, as re-

corded on the third day after the original attack, we attributed to accidental omission of the prescribed therapy. We are aware of the glaucomas complicating anterior uveitis, and we like to believe that in two eyes as angrily red as this patient's were that the slitlamp and corneal microscope would have revealed a cell or two in the anterior chamber. This was not the case. We also believe that, instead of promptly relieving the condition, eserine would have made it much worse had a uveitis been present. Inflammatory diseases of the uveal tract may be attended by increased pressure of the eyeball by purely a mechanical process, as Dr. Lehrfeld said. In this case we believe that the mechanism was the same, but that the basic cause was not inflammatory but allergic in nature.

(Signed) Milo H. Fritz,
New York, New York.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

GENERAL METHODS OF DIAGNOSIS

Cristini, G. The value and limits of color perimetry. *Rassegna Ital. d'Ottal.*, 1946, v. 15, Sept.-Oct., pp. 381-405.

For practical purposes, colored test targets are really useful only in the central fields. (13 figures.)

Eugene M. Blake.

Duguet, J. Functional visual examination in aviation. *Ann. d'Ocul.*, 1946, v. 179, Sept., pp. 463-480.

The methods and instruments most frequently used in the visual examination of French and other aviators are briefly discussed. Visual acuity is preferably tested in France with the optometer of Beyne with illumination of 15 lux at a distance of 5 meters and the broken ring of Landolt. The oculomotor mechanism is preferably measured with the Maddox rod or the Remy diploscope. At the International Conference of Aviation in Montreal in 1946, the maximum adopted for pilots of civilian transports and military aviators were: esophoria, 10 degrees; exophoria,

5 degrees; hyperphoria, 1 degree. Binocular and stereoscopic vision is measured stereoscopically and with the Howard-Dollman apparatus, in which 30 mm. is the acceptable limit at 6 meters. Color vision is measured first with isochromatic charts and then with colored lanterns. Of isochromatic charts, the ninth edition of Ishihara published by Lewis in England in 1943 is considered satisfactory. The American edition published by the American Optical Company was found subject to a 25-percent error. Of the lanterns used, the chormetre of Mehaute-Guerin and the lanterns of Green and Giles Archer were considered most satisfactory. Night vision may be satisfactorily tested with the AAF night vision tester (Eastman U.S.A.), Royal Air Force hexagon (Gr. Brit.), the method of Beyne and Worms (French), the Hecht-Schaler night vision tester (USA), or the adaptometer of Wilson (Gr. Brit.). (13 references.)

THERAPEUTICS AND OPERATIONS

Arentsen, Juan. Infiltration of penicillin dissolved in 2-percent novocaine in localized bacterial inflammations. *El Día Médico* (Buenos Aires), 1946, v. 18, Dec. 9, pp. 1950-1954.

The author advocates the infiltration of infected tissues with a solution of 3000 Oxford units of penicillin per c.c. of procaine solution. The penicillin is not applied on or in the infected wound but the surrounding inflamed tissue must be infiltrated. It can be applied in any stage of the evolution of infection. The treatment is painless, efficacious, and can be used in inflammations of the eye and its adnexa as safely as in other organs.

F. H. Haessler.

Avgushevich, P. L. Oxygen therapy in ocular war injuries. *Vestnik Oft.*, 1945, v. 24, pt. 4, pp. 28-31.

Subconjunctival oxygen insufflation is advocated for the absorption of traumatic corneal exudates, stimulating epithelization, and relieving subjective symptoms. It is also effective for stimulating the absorption of lens masses

in the anterior chamber in traumatic cataract, and of fresh hemorrhages in the vitreous. The technic consists in insufflating oxygen subconjunctivally through a needle.

Ray K. Daily.

Benstein, I. I. The action of calcium iontophoresis on the specific sensitivity of eyes of tuberculous animals. *Vestnik Oft.*, 1946, v. 25, pt. 6, pp. 13-17.

A laboratory investigation of calcium iontophoresis in ocular tuberculosis is reported. In experimental corneal tuberculosis it affects favorably the course of the tuberculous process and reduces the local sensitivity. The application of iontophoresis produces no irritating symptoms, and alleviates the inflammatory phenomena. The development of tuberculous granuloma is arrested. The lesion becomes sharply demarcated from healthy tissue and never reaches caseation. The effect of the iontophoresis on the Mantoux reaction is less marked than the local effect, but nevertheless manifests itself by a shift towards desensitization. The lowered sensitivity of the skin was present in animals infected directly in the eyeball, as well as in those infected hematogenously.

Ray K. Daily.

Bursuk, G. G. Substitutes for protein therapy and their choice in war-time. *Vestnik Oft.*, 1945, v. 24, pt. 3, pp. 32-35.

As criteria of effectiveness of an injection of a therapeutic agent Bursuk used his evaluation of the clinical improvement and a measurement of the sedimentation rate. He found that injections of milk, cod liver oil, 1-percent potassium permanganate solution, sulphur, 10-percent sodium chloride solution, sterilized egg yolk, hot air, and water were equally effective. He con-

cludes that the favorable effect is due not to the specific action of the injected agent on the inflammatory process, but to the action of some products which appear to be liberated in the tissues of the patient in response to the irritation produced by the injection.

Ray K. Daily.

Carmi, A. Therapeutic action of cobra venom in ophthalmology. *Rassegna Ital. d'Ottal.*, 1946, v. 15, Sept.-Oct. pp. 437-439.

Carmi cites the advantages of snake venom in ocular therapeutics and quotes Calmette's extensive experiments with the poison of various classes of snakes. A weak solution of cobra venom instilled into the conjunctiva, has a sedative effect. Subcutaneously used it relieves the pain of neoplasms through vasodilation. The capillaries of the fundus undergo a similar dilation. It is thus useful in the optic nerve atrophy of arteriosclerosis and chorioretinitis. Other conditions said to be benefited by the venom are retrobulbar neuritis, retinal hemorrhages, myopic chorioretinitis, primary optic atrophy, and pigmentary degeneration of the retina. Eugene M. Blake.

Chentzov, A. G. Tissue therapy data at the Eye Clinic of the First Moscow Medical Institute. *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 30-34.

This form of therapy was tried on 66 patients with myopic degeneration at the macula, retinal hemorrhages, vitreous opacities, retinal detachment, optic atrophy, uveitis, and keratitis. The results were encouraging, if not as good as those reported by Filatov; he ascribes the disparity in results to faults in technic. He regards tissue therapy as a new method of foreign protein therapy, with action different

from that of lactotherapy. The effectiveness of mobilizing the resisting forces of an organism is generally recognized; biogenic stimulants bring additional strength to the regenerative powers of an organism attacked by disease.

Ray K. Daily.

Cossu, D. The use of Roentgen rays in the prevention of operative hemorrhage. *Rassegna Ital. d'Ottal.*, 1942, v. 11, March-April, p. 136.

For the prevention of operative hemorrhage and for the rapid absorption of extravasated blood, Cossu found X-ray treatment of the liver and spleen beneficial. It is indicated especially in operations where rubeosis iridis is a complication, or where one fears an intraocular hemorrhage. This treatment does not appear to be of value in severe trauma. Eugene M. Blake.

Fieandt, Olaf. A case of transitory myopia following radium irradiation. *Acta Ophth.*, 1941, v. 19, pt. 1, pp. 11-14.

Following a post-operative irradiation of the right eyeball for a basal cell carcinoma, with 30 mg. of radium for four hours, a 29-year-old student developed a transitory myopia, which cleared up within ten days. He had, in addition, some conjunctival irritation, and small atrophic spots in the conjunctiva of the lids. The myopia is attributed to edema of the lens, and to a ciliary spasm. Ray K. Daily.

Filatov, V. P. Methods of tissue therapy—biogenic stimulation. *Vestnik Oft.* 1946, v. 25, pt. 1, pp. 3-9.

In the process of perfecting keratoplasty Filatov developed a new therapeutic procedure, that of tissue therapy. The idea found scientific support in the fact that in tissue cultures in vitro

the addition of a fresh piece of tissue stimulates the growth of the old pieces. In 1933 Filatov published his method for increasing the transparency of a corneal transplant with partial corneal transplantation adjacent to the transplant. He later discovered that tissue preserved on ice acted more effectively than fresh tissue. From experiments with various tissues the conclusion emerged that any human, animal or plant tissue under certain unfavorable conditions develops products which, when used therapeutically, exert a favorable nonspecific effect on the entire range of ocular diseases. Biogenic stimulants were also found effective in diseases of the skin, the joints, and the female genital organs. The investigations were extended into the sphere of biology and botany. The germination of seeds was hastened by soaking them in tissue extracts. The investigations of the nature of the biogenic stimulants showed that trauma to plants leads to the formation of traumatinic acid, which belongs to the dicarbon group and is a powerful stimulant to cell proliferation. This acid was extracted from plants and was subsequently synthesized. Such biologic activators also develop within a sick organism under the influence of unfavorable conditions; perhaps the favorable effect on some diseases of chemical substances, cold, hunger, and intercurrent diseases may be attributed to the same process. The development of biogenic stimulants within an organism requires great care. The introduction of prepared stimulants is safer, can be done with less trauma to the organism, and acts equally well on lues, tuberculosis and some other diseases. Biogenic stimulants raise the metabolism of the cell, stimulate its function, and probably increase the fermentation capacities of

tissue albumens. This form of therapy is an adjuvant to other indicated therapeutic procedures, and should be used in conjunction with them.

The technic of tissue conservation and administration has changed with years of clinical experience. The newest form is that of implantation of autoclaved tissues and injections of their extracts. Detailed instructions are given for the preparation of extracts and their administration, and implantation of autoclaved cadaver skin, fresh organs, placenta, animal skin, and leaves of aloes. Ray K. Daily.

Foster, John. **Certain operations on the superior oblique.** *Brit. Jour. Opth.*, 1946, v. 30, Nov., pp. 676-682.

The relative rarity of direct operations on the superior oblique tendon impells the author to add three of his own. In the first a marked cyclophoria and vertical diplopia caused by traumatic paresis of the superior oblique were not relieved by tenotomy of the contralateral inferior rectus. By the method of Wheeler, the paretic muscle was advanced with a very good result. The second case was one of paresis of both the superior oblique and lateral rectus muscles of the same eye. At operation the internal rectus was recessed 6 mm., the outer halves of the superior and inferior recti were sutured to the insertion of the external rectus and the superior oblique was tucked 6 mm. Results were very satisfactory. In the third case traumatic adhesions around the inferior rectus could not be relieved by surgery. The superior oblique of the other eye was recessed 8 mm., with reasonably good results. (4 illustrations.) Morris Kaplan.

Gill, W. D. **An aid in facilitating postoperative dressing of the eye in**

patients with akinesis of lids. *Arch. of Ophth.*, 1947, v. 37, Jan., pp. 82-83.

Several years ago the author called attention to a simple method of maintaining postoperative closure of the eyelids after akinesis of the orbicularis oculi muscle had been employed, which consisted in sealing the lashes of the upper lid to the lower lid by means of a small droplet of collodion. More recently, in order to facilitate opening the lids and breaking the collodion seal, a short length of silk suture is introduced beneath the lashes after the eyelids have been closed and sealed with collodion. This can be accomplished before the sealing, but in such instances particular care has to be exercised to avoid incorporating the silk suture in the collodion droplet. When this silk suture is in position, its ends are brought together and draped onto the cheek below the eyelid; the two ends are tied together and the customary dressing is applied. When the time comes to inspect the eye, it is a simple matter to grasp the ends of the silk suture and, with gentle traction, to separate the lids. R. W. Danielson.

Hughes, W. F. Treatment of lewisite burns of the eye with dimercaprol ("BAL"). *Arch. of Ophth.*, 1947, v. 37, Jan., pp. 25-41.

Exposure of the eye to relatively small quantities of liquid or vapor lewisite produces a devastating ocular lesion. The progressive nature of such a burn is caused by the arsenical component of this war gas. To free the tissues from arsenic after exposure to lewisite, English workers synthesized dimercaprol ("BAL"). The work here reported from the laboratories of the Wilmer Ophthalmological Institute was devoted to the determination of

the optimum conditions for the use of this antidote, its mode of action and its limitations.

Lewisite is immediately hydrolyzed at the site of contact with the moist surface of the eye, liberating enough hydrochloric acid to produce a superficial corneal opacity. Within two to four minutes after exposure to lewisite followed by closure of the lids, all toxic arsenical material disappears from the surface of the cornea, and within two minutes the drug can be demonstrated in the aqueous. Beginning ten minutes after exposure and becoming well marked in thirty minutes, irreversible histologic changes in the cornea can be detected.

A single instillation of 5-percent dimercaprol solution or ointment within two to five minutes after exposure to lewisite effectively prevents the development of serious ocular lesions. This excellent therapeutic effect of dimercaprol is due, in part at least, to its rapid penetration and withdrawal of toxic arsenical material from the tissues before irreversible histologic changes have developed.

R. W. Danielson.

Iosefova, F. I. Antireticular cytotoxic serum in the therapy of ocular tuberculosis. *Vestnik Oft.*, 1946, v. 25, pt. 6, pp. 31-33.

A report of cases illustrates the effect of this remedy on the various types of metastatic ocular tuberculosis. It was found useful in chronic torpid keratitis profunda. It stimulates the physiologic function of connective tissue, and absorption and regression of the infiltration in the opaque cornea seems to follow. In patients with fresh chorioretinitis and periphlebitis it produces fresh hemorrhages and increased ret-

inal edema and should therefore be used with great caution.

Jona, Sergio. Investigations concerning the action of three drugs of the adrenaline group (sympamine, sympathol, veritol) on the normal human eye. *Riv. Neuro-Oto-Oft.*, 1941, v. 18, no. 4, pp. 312-334.

The author administered the drugs named in rather high doses to study their influence on pupillary diameter, intraocular vascular pressure, caliber of the intraocular vessels, and ocular tension. Measurements were performed before oral, intramuscular, or intravenous administration and for one hour after, at five-minute intervals. The dosage of sympamine was 3 centigrams oral or intramuscular, of sympathol 6 centigrams were given intravenously or 30 centigrams intramuscularly, and of veritol 1 centigram intravenously, 2 centigrams intramuscularly, or 7.5 centigrams orally. Eight full-page tables illustrate the action on the normal human eye: there were but slight variations of both the pupillary diameter and the ocular tension. Other authors have reported marked effects when the same drugs were given by instillation and subconjunctival injection. The retinal arteries showed a very slight dilatation after sympamine administration, and a slight but inconsistent constriction after sympathol and veritol. Sympamine produced a decrease of the intraocular arterial pressure which rose after administration of sympathol and of veritol.

Kenel, C. Leeches and hirudine in ophthalmology. *Ann. d'Ocul.*, 1946, v. 179, May, pp. 296-305.

After a historical resumé of the uses of leeches in ophthalmology and general medicine, the chemical and other qualities of a deuterio-albuminose, hirudine, which is prepared from the head of leeches, is described in detail. It inhibits blood coagulation, produces a basic increase of fibrinogen and globulins, is a local lymphagogue, is bactericidal and vasodilative. It is not toxic if given intravenously but does increase the toxicity of mercury. In iritis and vascular hypertension with eye or head pain the use of leeches or hirudine is followed by reduction of pain which is more rapid and complete than that which follows the use of artificial leeches. Leeches infected with anthrax did not communicate the disease to experimental animals. The relief of a pain following the use of leeches is apparently due to their indirect action on the cerebrospinal fluid. Three applications of two leeches are used over the mastoid region at 36 to 48-hour intervals. In Switzerland the use of leeches has greatly increased during the past ten years, and more than 300,000 leeches were used in France during 1944. Hypertension in glaucoma is lowered and pain is greatly reduced after the use of leeches. Liquimine and dicouramine are not considered as effective as hirudine.

Klein, M. Surgical anatomy of the facial nerve. With reference to the technique of orbicularis block (palpebral akinesia). *Brit. Jour. Ophth.*, 1946, v. 30, Nov., pp. 668-675.

Klein describes the methods of akinesia as suggested by Van Lint and by O'Brien and decides that the chance of error with each is too great. By anatomical dissection he demonstrates that the main bifurcation of the trunk of the facial nerve is quite below the area used so that both methods can easily miss many of the fibers. It is suggested that the correct point for injection is the area below the condyloid process at the junction of the upper and middle third of the distance between the zygomatic arch and the angle of the mandible. (4 figures.)

Morris Kaplan.

Krasnov, M. L. The use of tecodine in ophthalmology. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 35-36.

The authors comments favorably on the use of tecodine, which is dihydroxydionin chlorhydrate, as a substitute for morphine. In ophthalmology it can be used as an analgesic and as a basal anesthetic in conjunction with local anesthesia. It is free from some of the disagreeable effects of morphine, and is much less habit forming.

Ray K. Daily.

Larsson, Sven. Surgical bone-free roentgenography of the eyeball. *Acta Ophth.*, 1941, v. 19, pt. 1, pp. 1-10.

This method is similar to the one proposed by Franceschetti in 1934. The medial surface of the eyeball is exposed through a conjunctival incision, and the rectus internus is separated from the eyeball, the film applied to the surface of the eyeball as far back as the posterior pole, and the X rays directed from the temporal side. For exact localization of nonmagnetic foreign bodies, the film is applied as close to the suspected site of the foreign body as possible, and two exposures are taken. As an indicator the author uses a fine needle point introduced into the episclera. If the X-ray film shows that the foreign body is located at a distance from the indicator, the indicator is removed, reintroduced at another spot, and another X-ray picture taken; this is repeated until the indicator is found to lie exactly over the foreign body. In this fashion the author succeeded in extracting two nonmagnetic foreign bodies from eyes with opaque lenses. This method of localization is particularly suitable for fine nonmagnetic splinters that lie close to the posterior pole. (4 illustrations.)

Mata, Pedro. Vitamin P in ophthalmology. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Dec., pp. 1256-1265.

Mata reviews the known data on vitamin P and advocates its use as an antihemorrhagic agent. He found it very effective in preventing postoperative hemorrhage after dacryocystorhinostomies, and because of its effect on capillary permeability it exerts a favorable effect in the various types of iritis.

Ray K. Daily.

O'Brien, C. S. Ocular surgery. *Arch. of Ophth.*, 1947, v. 37, Jan., pp. 1-7.

No excuse exists for poor anesthesia.

An apprehensive and uncooperative patient is not conducive to good surgical performance. Preoperative sedation is indicated in all patients. Paralysis of the muscles of lid closure is indicated in any operation in which the globe is opened. O'Brien injects typhoid H antigen vaccine intravenously, in a dose of 10,000,000 to 15,000,000 bacilli, two days before cataract extraction and in a dose of 15,000,000 to 20,000,000 on the next day. A slightly modified Stallard suture is satisfactory. The keratome and scissors incision is much more easily made and is safer than the full Graefe knife incision, although it is less spectacular. Air injected into the anterior chamber keeps the angle open. One eye only need have a dressing. The patient may be allowed to sit in a chair or lie in bed, as desired.

In cataract combined with primary glaucoma the author uses a combined anterior sclerectomy (Lagrange) and cataract extraction. In acute narrow angle glaucoma a basal iridectomy is indicated. In chronic wide or narrow angle glaucoma, in which the tension is not too greatly elevated, in eyes with small visual fields, or as a second operation, cyclodialysis is good practice.

It seems wise to do a two-stage operation in cases of convergent strabismus, for with this method there are few overcorrections. Undercorrection is expected after the first operation. In most cases of convergent strabismus of over 15 degrees a recession of 5 mm. is made on one internal rectus muscle. After three or more months the lateral rectus is shortened, or shortened and advanced, depending on the amount of deviation that remains. In recession a muscle clamp is never used, since 2 to 3 mm. of muscle is lost. Only a squint hook is used, and the sutures are placed as close to the insertion of

the muscle as possible. The muscle sheath is always kept intact.

For tumors of the orbit, a wide lateral canthotomy, extending about one centimeter back from the bony orbital margin, is made, and the incision is extended upward or downward in the conjunctival fornix.

R. W. Danielson.

Paltzeva, T. A. Subconjunctival injections of laked blood in the treatment of corneal diseases. *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 34-36.

Three drops of the patient's blood are added to one half c.c. of distilled water and when the blood is hemolyzed 0.2 c.c. of the mixture is injected subconjunctivally close to the limbus. The tabulated data show that the treatment has no objectionable features, that it ameliorates discomfort, and stimulates epithelization, vascularization, and absorption of hypopyon. It is effective in superficial herpetic keratitis, and mild corneal ulcers. The general reaction to this treatment consists in an increased number of leucocytes and erythrocytes.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Aquilar Muñoz, Jose. **The use of Remy's diploscope in refraction.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Sept., pp. 878-900.

Since 1940 the author routinely uses Remy's diploscope. It is a simple apparatus and easy to use. It should be used preferably for hypermetropia and

patients with imperfect or absolute faults of binocular vision, and for the diagnosis and treatment of the heterophorias, especially the exophorias. By using this instrument the prescription of prisms becomes more accurate.

J. Wesley McKinney.

v. Bahr, Gunnar. *Investigations into the spherical and chromatic aberration of the eye, and their influence on refraction.* Acta Ophth., 1945, v. 23, pt. 1, pp. 1-47.

The literature is briefly reviewed, and the author's investigation, using an aberrometer constructed on Scheiner's principle, is reported in detail. The investigation was made in two series: in one, 32 medical students and doctors were tested with red and blue rays, transmitted through a cobalt filter; in the second series, 25 subjects were examined with monochromatic light from a monochromator. The data furnished by these tests were then compared with data derived from refractions, according to Donders, using the same monochromatic illumination on test charts. The tabulated data show that there is, as a rule, positive aberration in the whole of the pupillary field, but that it varies considerably in strength; not infrequently, the aberration is negative, and sometimes it is positive in the central part of the field, and negative in the peripheral part. When the vision is clearest, neither the cusp of the caustic surface nor the narrowest cross section of the refracted pencil of rays is placed on the retina; a cross-section of the caustic surface is situated on the retina, which is nearer to the refracting system than the cusp, when there is positive aberration, and further away when the aberration is negative. The data also show that the total astigmatism as found in the customary re-

fraction tests depends not only on the distance between the points where the paraxial rays intersect in the principal sections, but also on the aberration of the astigmatism. The table of chromatic aberration shows that there is no significant difference between the chromatic aberrations in the different peripheral parts of the optic system, and that in monochromatic illumination the wave length of the light affects refraction considerably. The visual acuity in pure blue light is decidedly lower than in red and green light. (3 figures, 9 tables.)
Louis Daily, Jr.

Burian, H. M. *Sensorial retinal relationship in concomitant strabismus.* Arch. of Ophth., 1947, v. 37, March, pp. 336-368.

The author describes and analyzes in great detail the sensorial-retinal relationship in concomitant strabismus. The analysis will be continued in a future issue of the Archives.

R. W. Danielson.

Hallett, J. W. *Unexplained amblyopia as a military problem.* Military Surg., 1946, v. 99, Aug., pp. 110-116.

These studies of bilateral as well as unilateral visual defects included only patients with no visible abnormalities in the eye. Obviously those with strabismus and anisometropia were not included. Malingering, an important feature of the investigation, was determined by the visual angle test. The vision, in the patients studied, was not better than 20/40.

Fifty-one cases were reported, thirty of bilateral amblyopia. Half of the patients with bilateral defects gave positive malingering tests but only two who had unilateral amblyopia malingered. Almost 75 percent of the patients had visual field defects such as tubular

fields, interlacing of color fields, and concentric contraction. Malingerers with bilateral amblyopia were considered as potential psychiatric problems. Tubular fields were associated with functional nervous disorders in a high percentage of cases.

Francis M. Crage.

Hardy, L. H., Rand, G., and Rittler, M. C. Effect of quality of illumination on the results of the Ishihara test. *Arch. of Ophth.*, 1946, v. 36, Dec., pp. 685-699.

Color vision determinations were made on 22 subjects employing various editions of the Ishihara test under standard daylight illumination and also with tungsten filament illumination. The daylight was provided by a Macbeth daylight lamp designed to operate at approximately 6,750° K. The tungsten filament illumination had a color temperature of approximately 2,848° K. When tungsten light is used as the illuminant, the performance scores attained by all of the deuteranomalous and deuteranopic subjects tested are higher than when daylight is used. The responses of protanopic and protanomalous subjects are little affected by this change. A substantial number of deuteranomalous subjects are sufficiently aided in giving normal responses by the incorrect use of tungsten light that they may be erroneously classified as normal. There is a decrease in the number of subjects who are correctly classified as to type of defective red-green vision when tested under tungsten light, as compared with the number so classified when tested under daylight, and an increase in the number of protanomalous and protanopic subjects who are incorrectly classified.

The authors stress the critical importance of strict observance of correct conditions of illumination during the

administration of polychromatic tests which employ test material seen by reflected light.

John C. Long.

Litinsky, G. A. Training of depth perception in the one-eyed. *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 11-15.

Litinski holds that monocular depth perception is possible if the observer can see the extent of the surface on which the objects are placed; with the surface invisible monocular depth judgment becomes 10 to 20 times poorer than binocular. Binocular depth perception is equally good with or without visibility of the surface. Litinsky agrees with Helmholtz that depth perception is an acquired function and believes that monocular perception can be acquired by training. On the basis of experience with 28 patients, Litinsky concludes that depth perception lost with the loss of one eye can be restored by training, and that best results in training are obtained in people with normal visual acuity. Training is most effective when exercises are done with objects that cannot be related to a visible surface such as ball playing, tennis, ping-pong, volley ball, and basket ball. The period of training requires not less than 10 to 15 days and 15-20 minutes daily. The vocational importance of depth perception justifies the establishment of training facilities in military and civilian hospitals.

Ludvigh, Elek. Bench for the teaching of ophthalmic optics. *Arch. of Ophth.*, 1947, v. 37, March, pp. 383-385.

The optical bench is an essential adjunct to laboratory instruction in elementary ophthalmic optics. The benches ordinarily employed are not designed for the teaching of ophthalmic

optics and have many features which are undesirable for that purpose. Ludvigh points out the difficulties experienced with the optical benches commonly available, and states how these are overcome in the bench here described.

R. W. Danielson.

Moore, R. F. Subjective "lightning streaks." *Brit. Jour. Ophth.*, 1947, v. 31, Jan., pp. 46-50.

Three oculists describe their subjective experiences with "lightning streaks." These streaks apparently occur after middle age, most usually in myopic eyes and perhaps more commonly in women. Sudden flashes of light occur along with the simultaneous appearance of spots before the eyes. They are very bright, occur in the outer fields mostly and move from above downward. They start in one eye but tend to become bilateral. They are associated with quick movements of the eyes and thus can be elicited at will. They are best seen at night and the eyes may be open or closed. Verhoeff, one of the subjects, attributes them to a shrinking and partial separation of the vitreous which then impinges on the retina and induces the stimulation.

Morris Kaplan.

Valerio, Mario. Jackson's cross cylinder in the determination of the axis of astigmatism. *Rassegna Ital. d'Ottal.*, 1946, v. 15, July-Aug., pp. 241-263.

Valerio reviews the history of the bicylindric lenses from the time of Stokes, in 1849, until its perfection by Jackson. The author considers the correct name to be bicylinders, rather than cross cylinders. In spite of its wide use in the United States the instrument is little known abroad. The author soon found the cross cylinder "absolutely indispensable for an accurate examina-

tion of the refraction" and proceeds to give a complete explanation of its construction and application, with illustrative cases and photographs. (4 figures.)

Eugene M. Blake.

Walker, J. P. S. Myopia and pseudomyopia. *Brit. Jour. Ophth.*, 1946, v. 30, Dec., pp 735-742.

Walker points out that many cases of pseudomyopia are missed in routine practice. It occurs mostly in the young, but it can occur at any age. As a safeguard the author suggests that all patients under 16 years of age be refracted after atropine has been instilled twice daily for three days. In some cases it should be instilled for two weeks before examination. The term pseudomyopia includes spasm of accommodation. Ten reports are presented of cases in which the patient seemed to desire more minus power than the refraction indicated; these were considered as due to spasms and were treated with atropine or orthoptic training or both with very good results. The fact is emphasized that pseudomyopia is just as likely to occur in the hyperopic and emmetropic patients as in myopic ones.

Weekers, R., and Roussel, F. Introduction to study of the critical flicker frequency for clinical purposes. *Ophthalmologica*, 1946, v. 112, Dec., pp. 305-319.

Critical flicker frequency or fusion frequency of flicker is the smallest number of periodic changes from light to dark per second which abolishes the subjective sensation of flicker. The authors have constructed an apparatus for the determination of the critical flicker frequency of circumscribed, central or peripheral retinal areas and have found parallelism, in diseased eyes, be-

tween the results of quantitative perimetry and the critical flicker frequency.

OCULAR MOVEMENTS

Adler, Francis H. **Physiologic factors in differential diagnosis of paralysis of superior rectus and superior oblique muscles.** *Arch. of Ophth.*, 1946, v. 36, Dec., pp. 661-673.

In cases of primary or congenital paralysis of a vertically acting muscle a differential diagnosis between paralysis of the superior oblique of one side and the superior rectus of the opposite side may be made on the basis of the following signs: Tilting the head is the most characteristic sign of paralysis of the superior oblique muscle. Tilting does occur with paralysis of the superior rectus, but is slight. The head is always tilted toward the side opposite the paralyzed eye. If the head is tilted by the examiner on the shoulder of the same side as the paralyzed eye, this eye will make an upward movement if the superior oblique is paralyzed. If the superior rectus is paralyzed, the eye either will not move at all or will move slightly downward.

A factor which may confuse the picture in primary or secondary paralysis of a vertically acting muscle is the occurrence of inhibitional palsy of the contralateral antagonist. When this is present, primary paralysis of the superior oblique may easily be mistaken for paralysis of the superior rectus. The physiologic bases for the various signs are discussed in some detail.

John C. Long.

Azzolini, Umberto. **Synkinesis between the levator palpebrae superioris and the musculus zygomaticus.** *Riv.*

Oto-Neuro-Oft., 1942, v. 19, Nov.-Dec., pp. 382-397.

An otherwise normal girl, eight years of age, had an almost complete left ptosis; the upper lid could not be elevated by any of the synkinetic innervations except in smiling. The homolateral zygomatic muscle is innervated by the seventh cranial nerve. The author assumes that there was a congenital heterotopic location of the nucleus of the levator palpebrae superioris, the cells of which were displaced into the neighborhood of the nucleus of the facial nerve. (4 figures.)

K. W. Ascher.

Cass, E. **Strabismus.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 126-160.

The author presents a detailed review of the literature concerning strabismus, especially from the etiological standpoint. (10 illustrations.)

J. Wesley McKinney.

Del Barrio, Alejandro. **Development and treatment of squint.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Sept., pp. 863-877.

The author agrees that the key to the development of squint is in the binocular vision, which if it develops normally produces no squint, even if there are other disposing causes. On the other hand, if this function is incomplete, a small alteration of the optic apparatus, sensorial or motor, is able to produce squint. It is thus that surgical as well as functional treatment is directed toward normalizing the binocular vision. J. Wesley McKinney.

Della Vedova, Ausano. **Laryngo-vestibular signs in syringobulbia.** *Riv. Oto-Neuro-Oft.*, 1943, v. 20, Jan.-Feb., pp. 29-39.

In three patients suffering from syringobulbia, spontaneous nystagmus was associated with laryngeal paresis. In two of them, the nystagmus was rotatory, counterclockwise, and associated with a right abduction paralysis of the larynx; in the third the laryngeal paresis was bilateral, and the nystagmus horizontal. This syndrome is of diagnostic significance in early stages of syringobulbia. K. W. Ascher.

Epstein, G. J. **Congenital vertical motor pareses.** *Arch. of Ophth.*, 1947, v. 37, March, pp. 369-374.

After discussion of the literature and a review of pertinent embryology, the authors conclude that congenital pareses of the extrinsic ocular muscles are due to errors in cleavage of the common premuscle mass, aplasia of the primitive head cavities and aplasia of the connections in the central nervous system. Of these, pareses of the first type are by far the most common.

Errors in cleavage are most likely to affect those muscles which are differentiated late in embryonic development. Therefore, of the vertical muscles, the superior rectus is by far the most commonly affected, the inferior rectus and the inferior oblique next and the superior oblique most infrequently. There is clinical evidence to support this view.

R. W. Danielson.

Ferrara, Aristide. **A case of Parinaud's paralysis.** *Riv. Oto-Neuro-Oft.*, 1942, v. 19, July-Aug., pp. 277-288.

Two years before admission, a 40-year-old farmer had become unconscious and had suffered a paralysis of his left arm, and diplopia. Corrected vision was 10/10 and 7/10 respectively; the visual fields were normal. Ophthalmoscopy revealed no pathologic changes. The eyeballs could be rotated

neither up nor down, and no convergence was possible; touching of the corneas produced contraction of the orbicularis but no flight movement of the bulbi. Compensatory eye movements were absent. The Wassermann reaction in the cerebrospinal fluid was positive. A luetic arteritis of the cerebral arteries was assumed and a juxtaventricular hemorrhage seemed to be responsible for the lesion involving the nuclei that govern the associated eye movements.

Fisher, E. M. **The practical significance of the voluntary convergence.** *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 10-11.

Whereas the role of the accommodation-convergence relationship in the pathogenesis of convergent strabismus is well understood, its role in straightening the visual axes in divergent strabismus is sometimes overlooked. In the effort to obtain parallelism of divergent eyes the exercise of convergence produces a spurious myopia, the nature of which can be established by skiascopic examination under atropine, and which should not be corrected with glasses.

- Fisher, E. M. **Errors in the conservative treatment of strabismus.** *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 6-9.

Listed as errors in the pattern of therapy of concomitant strabismus are improper selection of patients for delayed treatment, failure to prescribe the full correction, neglect to treat amblyopia, or to treat it inadequately, inade-

quate preparation for orthoptic training by preliminary refraction, the training of binocular vision in the presence of abnormal correspondence, and orthoptic training in the presence of a large angle of deviation of the visual axes.

Ray K. Daily.

Krewson, William E., III. Surgical methods of treating paralysis of the superior oblique muscle. *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 121-133.

No one standard sequence of corrective measures can be advocated for all patients. The plan of attack must be based on the measurements in the individual case. If a choice is permitted, weakening of a depressor muscle is undesirable; strengthening of a depressor or weakening of an elevator muscle is preferable, for there is greater need for binocular vision in the lower than in the upper parts of the fields. If there is marked overaction of the homolateral, antagonistic inferior oblique muscle, tenotomy of this muscle is probably desirable as the initial operation. In the usual case of paralysis of the superior oblique muscle most surgeons apparently first do a recession of the contralateral inferior rectus and then attempt a shortening of the paralytic superior oblique. Depending on measurements then obtained, these operations are supplemented by recession of the homolateral, overacting inferior oblique, advancement of the contralateral superior rectus or advancement of the homolateral inferior rectus. In cases of bilateral paralysis of the superior oblique, equalization and preservation of the remaining depressors are advisable.

Lopez-Dominguez, B. A classification of strabismus and its therapeutic implications. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Dec., pp. 1277-1283.

The proposed classification is based on disturbances of the function of each of the participating entities of the reflex act of seeing, namely, the organ of perception, the centripetal pathway, the center, the centrifugal pathway, and the motor apparatus. Refractive strabismus, which is divided into isometropic and anisometropic, may be caused by a disturbance in the eye itself and may be central in origin. The instability of the surgical results is attributed to the fact that frequently the surgical procedure has no relation to the etiologic factor, and it is pointed out that the prognosis is best in cases in which the deviation is due to refractive or muscular anomalies, amenable to direct correction.

Ray K. Daily.

Matteucci, P. Congenital defects of abduction. *Rassegna Ital. d'Ottal.*, 1946, v. 15, Sept.-Oct., pp. 345-380.

Deficiency or congenital absence of abduction is frequently associated with numerous other defects, especially with

paralysis of the third and seventh cranial nerves. At times malformations of the eyes, the face, the trunk or the extremities, and retraction of the globe are noted. Among 60 cases collected from the literature other disturbances of motility than defects of abduction were found 25 times, anomalies or malformations were reported 14 times, and retraction of the globe 23 times. Three cases are added by the author, and a histologic study made of one of them is given in detail. The literature is extensively reviewed. (2 tables, 6 figures.)

Eugene M. Blake.

Milietti, Mario. Contribution to the knowledge of multiple aneurisms of cerebral vessels. *Riv. Oto-Neuro-Oft.*, 1946, v. 21, May-Aug., pp. 141-152.

A woman, 54 years of age, had recurrent attacks of pain of the left eyeball and the region about it for about a year. She had complete left oculomotor paralysis, and a slight right hemiparesis. Cerebral arteriography showed a diffuse cerebral arteriosclerosis, a big aneurysmal enlargement of the left internal carotid artery and a smaller aneurysmal sac of the posterior communicating artery above the posterior clinoid. In his discussion the writer states that the paralytic symptoms were due to compression of the trunk of the third nerve by the posterior aneurysm, and the hemiparesis to the compression of the pes pedunculi. The writer calls this symptomatology a "syndrome of the aneurysm of the pes pedunculi region." (Bibliography and 2 figures.)

Melchiorre Lombardo.

Ogle, K. N., and Ellerbrock, V. J. Cyclofusional movements. *Arch. of Ophth.*, 1946, v. 36, Dec., pp. 700-735.

There is now agreement that the external muscles of the eyes can, in the

interest of maintaining binocular single vision, cooperate to provide cyclotorsions about the visual axes, which themselves may remain fixed. These movements have been designated as psychooptical reflex movements.

The authors discuss experiments utilizing stereoscopic methods of spatial localization, which show that these cyclofusional movements occur much more freely than was heretofore realized. In the main these movements take place with any change in the type and orientation of configurations in the visual field.

A statistical study of the data obtained from 400 subjects with astigmatism at oblique axes is presented. The results suggest that the eyes of these subjects maintain cyclotorsional positions that partially correct the declinations of the images which, in turn, arise from the meridional magnifications accompanying the correction of the astigmatic errors.

The correlation found emphasizes the stability of the organization between the retinal elements of the two eyes.

Scobee, R. G., and Green, E. L. Tests for heterophoria. *Amer. Jour. Ophth.*,

1947, v. 30, April, pp. 436-451. (8 tables, 9 references.)

Sergievsy, L. I. **Invisible strabismus, and the character of vision with both eyes open.** *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 4-5.

This is an analysis of 983 cases of strabismus; 62 cases with no deviation of the visual axis and no binocular vision are designated as invisible strabismus. Among 102 patients with periodic strabismus, vision not lower than 0.5 in the poorer eye was found in 23, binocular vision was present in 16, and simultaneous macular perception was present in 20 patients, of whom 10 had good vision. Of 98 patients in whom the visible strabismus became invisible, 42 developed binocular vision, 51 had monocular vision, and 5 had simultaneous perception. The data thus show that deviation of the visual axes may disappear with age, but the absence of binocular vision remains; the time required for parallellism of the visual axis to develop with glasses is 1 to 18 months; in half of the patients it was two to four months. With orthoptic treatment patients with monocular vision develop simultaneous macular perception in 12 to 14 days, but it may take 11 months; simultaneous perception develops into binocular vision in four to 10 months. When the deviation did not disappear under atropine, but did clear up after wearing of glasses, it required two months to develop simultaneous perception, and one to three months longer for the development of binocular vision.

Ray K. Daily.

Sergievsy, L. I., and Bilit, M. V. **The effect of prolonged atropinization on the refraction and on the angle of deviation in concomitant strabismus.**

Vestnik Oft., 1946, v. 25, pt. 4, pp. 15-17.

An analysis of their case histories shows that the attainment of complete paralysis of accommodation requires at least ten days of atropinization, and that failure of the visual axes to become parallel even after atropinization for ten days is not conclusive evidence that the wearing of glasses will fail to straighten the eyes. Atropine is apt to correct deviations of 20 degrees. An interesting feature is exhibited by two hypermetropic patients in whom atropinization produced no change in the refractive correction, but relieved a deviation of the visual axes of 20 and 10 degrees respectively. Among those in whom the eyes became straight are some in which the deviating eyes had a visual acuity of .01. There was obviously no stimulus for accommodation in such eyes; the important factor in the deviation and the straightening of the visual axes seems to be the accommodation of the fixating eye.

Ray K. Daily.

Strich, A. J. **Classification of strabismus.** *Illinois Med. J.*, 1946, v. 89, Jan., pp. 25-28.

The author classifies strabismus, on an etiologic basis, as anatomic and innervational. In the former a lesion in the motor apparatus of the eye can be demonstrated, and in the latter, no lesion in the motor apparatus can be proved, although there may be a lesion of the visual apparatus, or a disease of the central nervous system. The anatomic cause may be a difference in shape of the two orbits, a congenital or acquired abnormality of the external ocular muscles or injuries to the peripheral neuron of the third, fourth, and sixth cranial nerves (as in diph-

theria, Gradenigo's syndrome, lues, tuberculosis, and meningitis). Nuclear strabismus is caused by congenital aplasia, hemorrhage, infections, diabetes, and poisoning of the nucleus of the nerves, and supranuclear strabismus can be caused by encephalitis lethargica, multiple sclerosis, small hemorrhages, and tumors that involve supranuclear pathways. A discussion of the diagnosis of supranuclear lesions follows. Corpus striatum strabismus is usually caused by postencephalitic Parkinson's disease, paralysis agitans, or Wilson's disease.

Innervational factors frequently complicate anatomic strabismus or may be the only cause as in the Donder's type in which an excessive hyperopia brings about excessive accommodation. Convergent squint associated with congenital myopia is probably due to a conditioned reflex. Inasmuch as the patient can see objects only when held very close, he develops an association between vision and excessive convergence. Poor-vision squints develop exotropia if the poor vision is present at birth, esotropia if it comes on during the period of flux. Pseudoparalytic strabismus is an alternating convergent strabismus, simulating bilateral abducens paralysis. The patient alternately uses his left eye to see the right part of the field, and his right eye to see the left part, and thus never has use of the external rectus muscles. Associated vertical divergence is caused by intermittent excitations of the vertical divergence center. Overaction of the inferior obliques is synkinetic in origin. Excessive stimuli to the convergence center overflow to the adjacent center for action of the inferior obliques, thus causing unilateral or bilateral primary inferior oblique spasms. Most strabis-

mus has a combination of anatomic causes and innervational factors.

John B. Hitz.

Tassman, I. S. Complete unilateral ophthalmoplegia due to primary carcinoma of the sphenoidal sinus. *Arch of Ophth.*, 1946, v. 37, March, pp. 294-303.

A neoplastic, inflammatory, or traumatic process which involves the structures passing through the sphenoidal (superior orbital) fissure and the optic canal may result in pressure on these structures and cause an ophthalmoplegia. The condition has been described in the literature as the "orbital apex-sphenoid fissure syndrome." About 10 cases of the syndrome have been reported in the American literature since 1900.

Carcinoma of the sphenoidal sinus has five routes of extension. In order of frequency, these are: orbital, nasal, cranial, petrous and occipital.

An interesting case of the complete syndrome is reported which was due to lateral extension of a malignant process from the sphenoidal sinus that involved the structures which leave the adjacent cavernous sinus and enter the sphenoidal fissure and the optic canal.

Epistaxis was unusually severe and prominent. Together with headache, it was an initial symptom. Severe, sharp, knifelike pains radiated over the forehead, the right temple and both eyebrows, and were more severe over the right side. There was also a burning sensation of the scalp.

The ophthalmoplegia came on rather quickly. It was complete within six days after appearance of the first ocular signs. In most of the cases in which the syndrome is due to a malignant growth, the symptoms have a much

slower onset and are more gradual in their progress.

Since this case was reported, the author has had the opportunity to study two others. R. W. Danielson.

CONJUNCTIVA

Abkina, D. A., and Normark, I. P. **Conjunctival erythema in typhus.** *Vestnik Oft.*, 1945, v. 25, pt. 4, pp. 45-46.

Bluish-red oval spots in the conjunctiva about 2 mm. in size are diagnostic of typhus fever; they may precede the rash, and persist after the rash has disappeared. Microscopically these spots show a stasis in the arteriocapillary network immediately under the epithelium, proliferative perivascularitis, and hemorrhages. Among 45 patients with typhus 12 had conjunctival erythema. Ray K. Daily.

Arcuri, Domenico. **Conjunctival naevi.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, July-Aug., pp. 264-289.

The author asserts that the majority of malignant epibulbar tumors arise from naevi, and stresses the importance of biomicroscopic study of all such cases. By this method the delicate changes of initial malignant degeneration can be detected. The histologic changes are described and the disputed question whether they arise from epithelial or connective tissues is considered. Ascuri reports two cases and found it impossible to determine their origin microscopically. Every naevus which shows a tendency to increase in size should be excised and the removal followed by diathermy coagulation. (6 figures.) Eugene M. Blake.

Bruce, G. M., and Locatcher-Khorazo, D. **Primary tuberculosis of the**

conjunctiva. *Arch. of Ophth.*, 1947, v. 37, March, pp. 375-378.

A case of primary tuberculosis of the conjunctiva with involvement of the adjacent lymph nodes in a 9-year-old child is reported. Systemic extension did not take place, and the patient recovered under conservative treatment.

R. W. Danielson.

Chulia, Vincennte. **Actinic keratoconjunctivitis.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Dec., pp. 1253-1254.

A case of actinic keratoconjunctivitis in a 15 year old girl, with pale, fine skin, and red hair, is reported, and it is pointed out that a constitutional predisposition is an essential factor for the development of this disease.

Ray K. Daily.

Frouchtman, R. **A case of spring catarrh caused by light.** The favorable effect of antergan. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Dec., pp. 1247-1253.

A case of spring catarrh in which light was the principal active irritant is reported because of two interesting features. Porphyrinuria, negative pollen tests, and a history of liver disturbances in the maternal family justify the assumption that the photosensitivity was due to a hepatogenic disturbance in the porphyrin metabolism. The second point of interest is the quick therapeutic response to antergan, a synthetic antihistaminic.

Ray K. Daily.

Mairlot Nieto, Roberto. **Treatment of gonococcal conjunctivitis neonatorum.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 209-210.

The author has had good results in

treating patients with gonococcal conjunctivitis neonatorum locally with 30-percent solution of sodium sulfacetamide (Albucid). The instillations were given every half hour, day and night, for the first 48 hours, and every one or two hours on the following days. At the same time the eyes were washed with normal saline solution at frequent intervals. J. Wesley McKinney.

Poliak, B. L., and Gerasimenko, T. N. Epidemiology, clinical course, and sulfa therapy of gonoblenorrhea. *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 26-30.

The material comprises 42 patients with gonoblenorrhea, which was bilateral in 36. In 17 the cornea was involved, and in 11 it had perforating ulcers. No patient was admitted to the hospital earlier than four days after onset of the disease. Treatment consisted in insufflation of powder into the conjunctival sac and intramuscular or intravenous injections of the drug. The tabulated data show that intramuscular injections in children were as effective as intravenous injections in adults, and that the results following this form of therapy are better than those obtained by oral administration. Uncomplicated gonorrheal conjunctivitis is cured in this manner in five to seven days. No corneal complications ever developed after the administration of the drug began. The progress of infiltrates was arrested and the ulcers rapidly became clean. The sulfa drug frees the eye of infection, and at the same time inhibits epithelial growth. The rapidity with which the conjunctival sac becomes free of gonococci eliminates the danger of involvement of the second eye. Ray K. Daily.

Stern, H. J. Sulphapyridine-resistant Koch-Weeks conjunctivitis. *Brit. Jour.*

Ophth., 1946, v. 30, Dec., pp. 722-723.

In the East African Negro troops the author found much virulent conjunctivitis caused by the Koch-Weeks bacillus which did not respond at all to treatment with sulphapyridine.

Morris Kaplan.

Tranou. Treatment of trachoma with sulfonamide. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Dec., pp. 1284-1288.

A controlled clinical investigation of 95 children with palpebral trachoma is reported. The children were divided into groups which were treated by means of oral administration of sulfonamides, oral administration combined with local therapy, local application of sulfonamide ointment alone, and subconjunctival injections of sulfa drug solutions twice weekly for six weeks. Oral administration of sulfa drugs lead to improvement in many cases, but to few cures. Better results were obtained by a combined local therapy with oral administration of the drug. The best results were obtained from subconjunctival injections of irgamid. Sulfathiazole, because of severe reactions, is unsuitable for subconjunctival injections.

CORNEA AND SCLERA

Angius, T. Corneal involvement in Duhring's disease. *Rassegna Ital. d'Ottal.*, 1946, v. 15, July-Aug., pp. 290-297.

Duhring's disease is frequently confused with pemphigus and some writers consider it a form of the latter. The eruption is usually bullous but may be polymorphous and affects the skin of any part of the body. There is an eosinophilia of 10 percent in the blood and 90 percent in the bulla. The disease is

characterized by periods of remission, with a tendency to gradual subsidence. A case is described with ulceration of the cornea, in a 41-year-old man in whom the skin eruption had been present for 2 years. Eugene M. Blake.

Bakker, A. Some researches on the respiration of the cornea in albino rats. *Brit. Jour. Ophth.*, 1947, v. 31, Feb., pp. 100-108.

A description is given of the technique of studying the influence of various concentrations of carbon dioxide and the absence of oxygen in the surrounding atmosphere, on the cornea of anesthetised albino rats. With the help of artificial respiration it was possible to shut the animals in a tank, and to expose the eyes under otherwise normal conditions to the gas under investigation. It could be determined that the so-called selective permeation of carbon dioxide through the cornea is not probable. Absence of oxygen in the surrounding atmosphere does not inhibit normal life of the cornea. The corneas remained transparent for many hours in an atmosphere of 8 percent of carbon dioxide and 92 percent of nitrogen. Special attention was paid to possible pathologic changes in the corneas after the experiments were finished.

O. H. Ellis.

Balcet, C. Various forms of superficial punctate keratitis. *Rassegna Ital. d'Ottal.*, 1942, v. 11, March-April, p. 109.

Twenty-three cases of superficial punctate keratitis are described and from the observation of these, and from the study of the literature, Balcet believes that the name includes the infective form which has been seen often in the tropics. All of the different

forms are herpetic in origin. In tropical and subtropical countries conditions which favor development of the disease are the hot and moist climate, poor hygiene and nutrition, plus a certain avitaminosis.

Eugene M. Blake.

Blanchi, G. Primary adiposis of the cornea. *Rassegna Ital. d'Ottal.*, 1942, v. 11, March-April, p. 144.

The term primary adiposis of the cornea should be reserved for those cases in which no other severe ocular disease exists. It is a true lipoidosis of the cholesterine form, with a demonstrated disequilibrium of fatty metabolism. The cause is to be searched for in hormonal alterations, in the ovary, thyroid and hypophysis. Nor should the importance of the reticuloendothelial system be disregarded.

Two forms of corneal adiposis are recognized, the annular and the central discoid; the second form is considered a part of the annular type.

The literature is well abstracted and one case with histological study is reported. Eugene M. Blake.

Castroviejo, Ramon. Indications and contraindications for keratoplasty and keratectomies. *Trans. Amer. Ophth. Soc.*, 1945, v. 43, pp. 324-330.

The author bases his conclusions on the study of more than 600 keratoplasties and over 100 keratectomies. Keratoplasty gives the better visual acuity. With keratoplasty it is not rare to obtain vision of 20/20 while with keratectomy astigmatism and residual haziness reduce vision to 20/100 or less. In glaucoma, it is usually advisable to make a very large iridectomy to reduce the danger of anterior synechia and the recurrence of glaucoma. Very favorable for keratoplasty are central

opacities where the transplant will remain surrounded by healthy corneal tissue, keratoconus, and interstitial keratitis when the transplant will remain in contact with healthy corneal tissue. A high percentage of clear grafts may be expected with final vision averaging better than 20/50 and not infrequently 20/20. Less favorable for keratoplasty, but still likely to give a high percentage of transparent grafts are corneal dystrophies, superficial corneal opacities, tear gas burns without pannus formation, adherent leukomas, descemetocoeles following corneal ulcers or surgical procedure in or near the pupillary area, and interstitial keratitis with more extensive and denser opacity. Unfavorable for keratoplasty are corneal scars which include the pupillary area and extend to the limbus, extensive leukomas in which the transplant will be surrounded in more than one half of its circumference by dense scar tissue (keratectomy may improve vision or make the eye more favorable to undergo keratoplasty), band-shaped opacity, in which it is preferable to perform a partial superficial keratectomy, dystrophia adiposa, deep corneal burns with tear gas where preliminary superficial keratectomy is indicated, extensive corneal opacities caused by explosions that leave the cornea with a tattooed appearance, corneal opacities in aphakic eyes, extensive corneal opacities with superficial vascularization of the pannus type generally caused by burns, Fuchs's epithelial dystrophy, extensive corneal opacities with calcareous degeneration, corneal opacities caused by pemphigus, corneal opacities with pronounced nystagmus, and corneal opacities with extensive anterior synechiae.

Feigenbaum, A., and Kornblueth, W. Posterior ring abscess of metastatic origin in Behcet's disease. *Brit. Jour. Ophth.*, 1946, v. 30, Dec., pp. 729-734.

Behcet's disease is a constitutional disorder due to sepsis and characterized by aphthous stomatitis, recurrent ulcers, recurrent iridocyclitis, retinitis, optic neuritis, and skin eruptions on the lower extremities. The cause is usually streptococcus aureus.

In the case reported, the eye had a marked posterior ring abscess of the cornea and severe inflammation. The aqueous was cloudy, but no hypopyon was present. Posterior synechiae were numerous and there was a cataract. The tension was elevated. Despite large doses of sulphathiazole and daily paracentesis, the patient became worse and developed general septicemia. One million units of penicillin were given with rapid improvement; the eye, however, went on to phthisis bulbi.

Morris Kaplan.

Henkes, H. E. On the distribution of glutathione and vitamin C in the lens and cornea. *Ophthalmologica*, 1946, v. 112, Sept., pp. 113-128.

The object of the study was to determine the respective concentrations of vitamin C and glutathione in the various layers of lens and cornea. By means of a trephine, cylindrical pieces were removed from frozen corneas and lenses. These pieces were sectioned with the microtome at right angles to their axes. Alternate sections in groups of four were used for the glutathione and vitamin C determinations, which were made by iodine and dichlorophenol-indophenol titration, respectively. Lenses and corneas of cattle, guinea pigs, and rabbits were studied under normal conditions as well as in a state

of experimental scurvy. In the lens the highest concentration of vitamin C was found in the subcapsular layers and of glutathione in the perinuclear layers. In the cornea the subepithelial stroma contained more vitamin C and glutathione than any other layer. Under conditions of experimental scurvy, vitamin C disappeared from the two ocular tissues within 14 to 19 days. The glutathione content remained unchanged. Peter C. Kronfeld.

Hercus, John. Epidemic keratoconjunctivitis in Australian troops. *M. J. Australia*, 1946, v. 2, Dec. 14, pp. 838-840.

A series of 56 patients with epidemic keratoconjunctivitis is reported. The patients were soldiers, and only one eye was involved in 50 of the patients. All had some form of corneal involvement, either superficial punctate staining or deeper infiltrates. There was a thin, stringy discharge, and in most cases a marked blepharitis. Cultures were negative, and attempts to grow the virus were unsuccessful. Treatment consisted of atropine, penicillin drops (500 Units per c.c.), bandaging of the eye for the first three to four days, and silver nitrate applied to the lids. If blepharitis was marked, 2-percent solution of gentian violet was used on the lid margins. The disease generally disappeared within nine days. The epidemiology was not determined although some association was noted with periods of heavy rainfall.

Latorre, S., and Crespi, G. Treatment of herpetic keratitis with alcohol. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Sept., pp. 849-862.

The authors report good results obtained in the treatment of herpetic keratitis with 90 percent alcohol. The procedure is easy and is not dangerous. After instillations of cocaine, fluorescein is used to make the lesion more visible. Now the lesion is touched with the alcohol. The treatment may be repeated every three days until the lesion does not stain. They present 19 cases. In one the treatment failed because there was a secondary infection. (Illustrations.) J. Wesley McKinney.

Leopold, I. H., and Adler, F. H. Use of frozen-dried cornea as transplant

material. *Arch. of Ophth.*, 1947, v. 37, March, pp. 268-276.

Keratoplasty has reached the stage today at which the demand for donor corneas has exceeded the supply. The small supply is largely due to the difficulty in preserving all available corneal tissue until the time at which it is needed. With the present methods of preservation, corneal tissue held over seventy-two hours is believed to be unsatisfactory for transplantation. The purpose of the experiment was to determine the value of frozen-dried cornea for corneal transplantation, as suggested by the preliminary experiments with rat cornea of Weiss and Taylor.

Fifty-nine of the 75 transplanted frozen-dried corneas healed in the recipient corneas. In 19 of these 59 grafts corneal vascularization occurred. In 6 of the 59 "takes," infection was an outstanding and early complication, and in 9 corneal edema persisted. Of the 16 eyes in which the transplant failed to remain in position, neither lid nor corneal sutures were used in 12.

The authors report that frozen-dried corneal tissue can be transplanted to normal rabbit eyes without an unusual host reaction. However, not one of the 59 "takes" with frozen-dried cornea were transparent at any time during the six months of observation.

R. W. Danielson.

Mann, I. "Blue haloes" in atebtrin workers. *Brit. Jour. Ophth.*, 1947, v. 31, Jan., pp. 40-46.

Six male patients who worked with powdered atebtrin complained of seeing blue haloes around lights at night. They had pursued all ordinary protective measures and showed no dermatologic

evidence of sensitivity. They had no other ocular complaints and vision was normal. On slitlamp examination all presented the same picture. The conjunctiva showed a diffuse pale yellow stain in the interpalpebral space only; at the limbus there were numerous minute dark brown spots. The whole surface of the cornea was covered by very fine yellow-brown particles which were actually imbedded in the cytoplasm of the superficial cells.

Experiments with rabbits showed that the granules were taken up by the cells directly from the surface and not through a systemic route. Once they appeared in the cells they did not dissolve but remained until the cells were normally cast off. The haloes were obviously a diffraction effect due to the opaque granules. The complaints were very mild, and disappeared without sequel in about two months after cessation of exposure.

Olontzeva, M. V., and Pokrovsky, A. I. Denig's operation and transplantation of preserved tissue by Filatov's method in the treatment of trachomatous pannus. *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 27-30.

Both operations consist of implantation of a transplant above the cornea parallel to the limbus; they differ in that Denig uses an autoplasmic transplant of fresh tissue and Filatov uses a homoplasmic transplant of preserved tissue. The authors used one procedure in one eye, and the other in the other eye, and selected subjects in whom the process was equally advanced in both eyes. During the occupation of Voronezh by the Germans this study was interrupted and Olontzeva perished.

Four years later, when the invaders were expelled, some of the patients returned and the results of the operations were checked.

The most important common factor is the surgical site above and parallel to the limbus. Implantations in other places on the eyeball gave inferior results. Transplantation of preserved tissue after Filatov has the advantage of more rapid absorption and a more pleasing cosmetic effect, but with this goes the disadvantage of a more rapid termination of the action of biogenic stimulants and the need for a repetition of the procedure. The effect of both procedures is usually temporary. Prolonged existence of severe pannus leaves as a consequence irreversible corneal cicatricial changes, and therapy should be energetic to shorten the course. Both Denig's operation and Filatov's procedure serve to stimulate regenerative processes.

Thygeson, P. **Marginal corneal infiltrates and ulcers.** *Trans. Amer. Acad.*

Ophth., 1947, Jan.-Feb., pp. 198-209.

Marginal corneal ulcers are by far the most common corneal disease in this country. They are usually secondary to conjunctival and systemic disease. The most frequent types are the simple catarrhal, ring, and chronic serpiginous (Mooren's ulcer). In a detailed study of 200 consecutive cases of marginal ulcer, 180 were catarrhal, 14 ring, and 6 serpiginous. Of the 180 catarrhal ulcers, 156 were secondary to chronic catarrhal conjunctivitis, 12 to acute catarrhal conjunctivitis, 4 to endogenous conjunctivitis, and 8 without associated conjunctivitis. Staphylococci were isolated in 133, diplobacilli in 11, Koch-Weeks bacilli in 8. Coincidental blepharitis and conjunctivitis were a constant feature of ulcers caused by staphylococci and diplobacilli. In the treatment of the staphylococcal group, 5-percent sulfathiazole ointment, penicillin ointment, and 1:5000 oxycyanide with ammoniated mercury were most efficient. Staphylococcal toxoid was a successful adjunct in some cases. Topical applications to the ulcer apparently did not shorten its course, as did the treatment of the conjunctiva and lid margins with sulfonamides. There was no evidence that riboflavin or other vitamin deficiencies were a predisposing cause to marginal ulceration. Of the 14 ring ulcers, 3 were associated with bacillary dysentery, 2 with influenza, 1 with periarteritis nodosa, 2 with arthritis deformans, and 1 with lupus erythematosus. Ring infiltrate and ulcers secondary to staphylococcal conjunctivitis responded well to penicillin ointment. In one case due to bacillary dysentery, the use of sulfonamides was followed by rapid improvement. Paracentesis with intravenous typhoid therapy was also possibly of

value. In the treatment of chronic ser-piginous ulcers sulfonamides and penicillin were without effect. Gifford's delimiting keratotomy apparently prevented advancement in some. Bacterial and other allergies may have been a causative factor in some cases. Marginal keratitis with acne rosacea is believed to be due to secondary staphylococcic infection.

Van Veelen, A. W. C. Bilateral spontaneous rupture of Descemet's membrane. *Ophthalmologica*, 1946, v. 112, Sept., pp. 149-154.

A 32-year-old imbecile suddenly, and apparently spontaneously, developed a circumscribed clouding and thickening

to three times normal of the cornea of first one eye and then the other. The clinical picture closely resembled that of acute hydrops of the cornea due to rupture of Descemet's membrane as it occurs in keratoconus, but all other signs of this disease were absent. One eye was enucleated because of marked proptosis and threatening perforation. In the other eye the area of corneal edema became regressive under conservative therapy and finally healed, leaving behind only a slightly protruding superficial corneal scar. Histologic examination of the enucleated eye revealed a primary rupture of Descemet's membrane with consequent severe edema of the stroma and secondary enzymatic breakdown of corneal tissue to the point of cavity formation. The cellular reactions were regenerative and reparative, rather than inflammatory. The question arises whether further observation will disclose signs of keratoconus. The author believes that self-inflicted injury can be ruled out.

Peter C. Kronfeld.

Zondek, Bernhard, and Bromberg, Y. M. Treatment of keratitis rosacea with small doses of testosterone. *Nature*, 1947, v. 159, Feb. 1, p. 171.

Six patients with keratitis rosacea gave a positive intracutaneous test with testosterone. Tests with several other steroid hormones were negative. Striking improvement of the ocular condition in all the patients followed the intracutaneous administration of increasing doses of testosterone. When facial rosacea was present this also was markedly improved.

Despite the favorable results obtained, allergy to testosterone seems to be a cause in a high percentage of cases.

UVEAL TRACT, SYMPATHETIC
DISEASE, AND AQUEOUS
HUMOR

Arruga, H. The simultaneous detachment of the choroid and the retina after a cataract operation. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 119-125. (See Section 9, Crystalline lens.)

Cavallacci, G. Uveoparotitis (syndrome of Heerfordt) and benign lymphogranulomatosis (disease of Besnier-Boeck-Schaumann). *Arch. di Ottal.*, 1946, v. 50, July and Aug. pp. 154-168.

Cavallacci reports one case of Heerfordt's disease. The patient had bilateral parotitis, and bilateral anterior chronic uveitis accompanied by recurrent mild fever. Absence of involvement of the cranial nerves is notable; most commonly involvement of the facial nerve is reported. Physical examination revealed mild hepatosplenomegaly and diffuse and painful swelling of the lymphatic glands. X-ray examination showed hilar adenopathy.

The intradermal reaction to tuberculin was positive. Histologic examination showed evidence of a reticuloendothelial disturbance, confirmed by monocytosis produced by adrenalin contraction of the spleen and by a study of smears following sternal puncture.

Four etiologic factors have been considered by the various authors: epidemic parotitis, syphilis, tuberculosis, and infection by an unknown virus. The unknown virus hypothesis has been championed primarily by Pautrier. He has shown in a very extensive monograph a great similarity between Heerfordt's disease and the disease of

Besnier-Boeck-Schaumann, and believes that Heersfordt's disease is a cephalic localization of the latter, which is a complex picture that includes lupus pernio of Besnier, cutaneous sarcoidosis of Boeck and benign lymphogranulomatosis of Schaumann. It is a lymphatic disease with a benign course and is to be differentiated from malignant lymphogranulomatosis of Hodgkin-Paltauf-Sternberg.

A comparative histologic picture is common to the two diseases, characterized by involvement of the connective tissue with isolated or confluent nodules, of varied size, which are composed of aggregates of epithelioid cells, a minimum of lymphoid cells, and occasional giant cells. The most important finding is the absence of degenerative changes and caseation. Mickulicz disease and Sjögren disease may also be a part of the syndrome of Besnier-Boeck-Schaumann.

A similar histologic picture can be obtained in many disease processes, and reticuloendotheliosis is not a response to a specific organism but rather the reaction to any one of many organisms which can call forth an immunizing allergic change. Cavallacci points out that his patient showed a positive tuberculin test, and favors this as the etiologic agent in his case.

Francis P. Guida.

Chavarria, F. A. The importance of the ophthalmoscopic examination in conditions affecting the external parts of the eyes. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 161-169.

The author insists on the routine ophthalmoscopic examination even in those patients who complain of external conditions of the eyes. A patient was referred to him for operation on a

pterygium of the right eye, which had almost reached the pupillary margin and obstructed his vision. Fundus examination revealed a tumor of the choroid of the right eye which necessitated enucleation of the eye. (7 illustrations.) J. Wesley McKinney.

Dean Guelbenzu, Manuel. Colloidometry of the aqueous humor. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, Dec., pp. 1266-1276.

Dean Guelbenzu reports his colloidometric studies of the aqueous humor in various ocular diseases. There is an increased concentration of albumen in inflammations of the iris, ciliary body, and anterior part of the choroid, in corneal diseases accompanied by pericorneal congestion, in deep inflammations of the conjunctiva, in limbal phlyctenular keratitis, in acute inflammatory glaucoma, and after trauma which produces a sudden drop in tension. It is apparent that there is an inflammation of the ciliary body, and an alteration of vascular permeability in the region of distribution of the long ciliary arteries or the arteries anastomosing with them. The increased colloid content of the aqueous indicates a more or less pronounced cyclitis, and this sign may be the only evidence of a painless, quiet iritis. (Illustration.)

Ray K. Daily.

Gsell, O., Rehsteiner, K., and Verrey, F. Iridocyclitis following leptospirosis pomona. Ophthalmologica, 1946 v. 112, Dec., pp. 320-334.

The leptospiroses comprise a group of diseases of worldwide distribution due to infection with various species of pathogenic leptospira. The best known leptospirosis is infectious jaundice or Weil's disease of which iridocyclitis is a characteristic and fairly

common complication. An acute, infectious, chiefly meningitic disease occurring characteristically in swineherds has been found to be a leptospirosis, due to infection with *Leptospira pomona*. A typical case of this disease occurred in a young man whose job it was to clean a large pigpen. Eleven days before the onset of the systemic disease, he had sustained an incised wound on one hand while at work. The wound "healed poorly," but did not cause any particular discomfort. The systemic disease took the course of a mild serous meningitis that subsided in three weeks. The leptospira could be cultured from the patient's blood on the third and fourth day, but not thereafter. Three months later the patient developed a mild iridocyclitis in one eye with a fibrous exudate that changed later on to precipitates and small brownish-gray nodules at the pupillary border. At the height of the iridocyclitis aqueous was aspirated and found to contain agglutinins for *Leptospira pomona* in significant concentration (in contradistinction to aqueous from other patients). "Since any other cause of the iritis could be excluded, it can only be regarded as a late complication of leptospirosis." The fact that the aqueous contained chiefly lymphocytes instead of the polymorphonuclear leukocytes which one would have expected to find in a fairly acute iritis, is stressed as another possible characteristic of the iridocyclitis due to leptospira.

Peter C. Kronfeld.

Johnson, L. V., Fried, N., Broadus, C. C., and Lamfrom, H. Use of neutralizing antibody test in diagnosis of human toxoplasmic choroiditis. Arch. of Ophth., 1946, v. 36, Dec., pp. 677-684.

The procedure for the neutralizing antibody test for toxoplasma is described. Suspected serum is mixed with a suspension of the organism from mouse brain. This mixture is injected beneath the skin of a rabbit and the size of the lesion produced is compared with the lesion produced by the injection of the suspension of organism alone. In positive tests the antibodies in the serum inhibit the development of the skin lesion in the rabbit.

Thirty-two selected patients with chorioretinitis were tested; 20 of these gave positive reactions in the neutralizing antibody test. Cerebral calcification in patients who had toxoplasmosis with chorioretinitis was not observed when the age of onset was known to be over 15 years. If the disease was present at birth, calcification was evident.

A mother with reactivated toxoplasmic choroiditis and a woman who was probably congenitally infected each gave birth to a normal child. Two children probably infected congenitally with toxoplasmosis had younger siblings-german with antibody protection but no demonstrable infection. A case of chronic toxoplasmosis is described in which a quiescent chorioretinal lesion became activated during each of three pregnancies. (Color drawings of chorioretinitis.) John C. Long.

Jona, S., and Sartori, A. Heerfordt's syndrome, a particular variety of Besnier-Boeck-Schaumann's disease. *Riv. Oto-Neuro-Oft.*, 1942, v. 19, Sept.-Oct., pp. 289-312.

A woman, 60 years of age, had bilateral iritis, bilateral parotid tumor, and paresis of her left seventh nerve. Biopsy of the tumor led to the diagnosis "Reticuloendotheliosis Besnier-

Boeck-Schaumann, subtype Heerfordt's syndrome." A tuberculous etiology was excluded. The authors assume that the syndrome was caused by a hitherto unidentified virus. (8 illustrations, bibliography.) K. W. Ascher.

Longhena, Luisa. The recurrent hypopyon-uveitis associated with mucocutaneous changes. *Riv. Oto-Neuro-Oft.*, 1946, v. 21, March-April, pp. 108-131.

Five cases are reported of a syndrome characterized by a typical uveitis associated with recurrent hypopyon of sudden onset, alternately in one eye or the other, and lesions of the mucous membranes and skin. A woman, 36 years of age, exhibited the typical eye symptoms, calcification of hilar glands and a positive tuberculin test. The vaginal mucous membrane presented superficial ulcers at each recurrence. Four other patients also had positive evidence of tuberculosis. After a long discussion of the different theories of the etiology of this disease the author concludes that the clinical and radiologic demonstration of pulmonary and extrapulmonary tuberculosis strongly suggests that the disease is a form of tuberculosis. (Bibliography.)

Melchior Lombardo.

McLean, D. W. An unusual case of intra-ocular hemorrhage. *Brit. Jour. Ophth.*, 1946, v. 30, Dec., p. 758.

Bleeding occurred from a strand of persistent pupillary membrane after very light trauma. After uneventful healing, the strand remained and in it could be seen a patent blood vessel in which movement of blood could be observed. Morris Kaplan.

Neubert, F. R. Posterior uveitis in a case of sarcoidosis. *Brit. Jour. Ophth.*,

1946, v. 30, Dec., pp. 724-728.

The author could find no record of posterior uveitis due to sarcoid and presents this case report as the first in the literature. In a young man who stated that his vision had rapidly deteriorated after looking at an eclipse, both fundi showed disseminated choroiditis with extensive scarring and pigment deposition. No diagnosis was made until he later developed signs of pulmonary tuberculosis with intestinal involvement. Resection of the cecum revealed sarcoidosis. Without further treatment, his general health and his vision improved. The fundus pictures remained the same. (2 figures.) Morris Kaplan.

Prosser Thomas, E. W. So-called triple symptom complex of Behcet. Brit. Med. Jour., 1947, Jan. 4, pp. 14-16.

In 1937 Behcet described an entity that consists of grave ocular disease and ulcers of the mucosa and external genitals. This is the first case to be reported in England. Eventually one eye had to be enucleated. Pathologic examination of the ocular tissue was not diagnostic. There was complete retinal detachment, gross intra-ocular hemorrhage, mainly subretinal, and marked patchy thickening of the ciliary body and choroid. (References.)

Bennett W. Muir.

Samoilov, A. I. Present day conception of the pathogenesis of intraocular tuberculosis. Vestnik. Oft., 1946, v. 25, pt. 6, pp. 3-7.

Samoilov believes that traces of an old tuberculous intrathoracic process can be found in the intrathoracic lymph glands or in the pulmonary parenchyma in every case of ocular tuberculosis. The bacilli circulating in the blood are arrested in the vascular

labyrinth of the choroid and set up a small symptomless focus, which rapidly becomes and remains latent. At some future time lowered resistance permits the process to become active and at that time it is the only active tuberculous process in the organism. Samoilov's method of tuberculin therapy with focal reactions is based on this pathogenetic hypothesis.

GLAUCOMA AND OCULAR TENSION

Boxill, W. M. de C. The flap sclerotomy in the treatment of glaucoma. Brit. Jour. Ophth., 1947, v. 31, Feb., pp. 72-78.

The author describes in detail the flap sclerotomy which is Sir Richard Cruise's modification of the idea originated by Herbert in 1907. It has been used successfully in acute congestive glaucomas as well as chronic glaucomas for which it was designed. Under a conjunctival flap with corneal splitting a blunt triangular sclerotomy with corneal hinge is made. Postoperatively gentle massage is performed to delay primary union. After a permanent filtering cicatrix is produced the massage is discontinued.

O. H. Ellis.

Braitseva, M. K. Campimetry in the study of glaucoma. The effect of decompressing operations on the retinal edema and ophthalmotonus. Vestnik Oft., 1946, v. 25, pt. 5, pp. 7-12.

A tabulated report is given of a study of the effect of an Elliott operation on the size of the central and peripheral field and the ocular tension in 16 patients with glaucoma. An enlarged blind spot, found preoperatively, and interpreted as a sign of retinal edema, was reduced to normal immediately af-

ter the operation when the tension was subnormal. The blind spot remains within normal limits for at least ten days. After that the parallelism between the size of the blind spot and the intraocular tension does not continue. After six to eight weeks the enlargement of the blind spot recurs, and vision falls. There is apparently a constant parallelism between the scotoma due to retinal edema and visual deterioration. Another significant table contains the data on 138 glaucoma patients followed from one to ten years. It clearly shows a progressive deterioration of vision with a stable, normal ocular tension. At the end of one year, more than half of the patients retained their preoperative visual acuity; at the end of three years this was true of only one third of the patients, and at the end of ten years of only 11 percent. At the same time the tension remained normal in 92 percent of the eyes. The data support the conception of glaucoma as an initial retinal edema which gradually leads to irreversible atrophic changes of the nerve tissue, manifested in the late stages by peripheral contraction of the field or ring scotomas.

Ray K. Daily.

Cruise, Richard. The production of a filtering cicatrix in glaucoma. *Brit. Jour. Ophth.*, 1947, v. 31, Feb., pp. 65-72.

Cruise presents the microscopic study of an eye upon which he had successfully performed his hinged-flap sclerotomy twelve years previously. The subconjunctival drainage area and corneoscleral tract were largely filled with a sponge of very delicate connective tissue. The walls of the tract were lined in part by definite endothelium; elsewhere the sclera was bare. In the

latter areas the sclera had undergone no apparent change since the day of the operation. (10 figures and photomicrographs.)

O. H. Ellis.

Dashevsky, A. I. New pathways for the study of ocular tension. *Vestnik Oft.*, 1946, v. 26, pt. 5, pp. 18-27.

This is a preliminary report, with tabulated data on elastotonometry with a new instrument designed by the author. The technique allows a clearer recognition of the two basic factors in measurements of ocular tension: the true intraocular pressure, and the coefficient of the ocular reaction to pressure exerted by the instrument. The author presents a formula for calculating the coefficient of the ocular reaction to pressure, and the true intraocular pressure. The resolution of the data into their basic components permits a better understanding of the factors involved in the maintenance of the hydrodynamic ocular equilibrium. The reaction of the eye to pressure depends on the vascular apparatus of the eye, and the data show that it is directly proportional to the difference between the diastolic retinal pressure and the true intraocular pressure. When the two are equal, the coefficient of reaction becomes equal to zero. This indicates that the reaction coefficient is due to the difference in pressure on either side of the vessel wall, and that the vessel wall is the anatomic site of the process interpreted by the coefficient of reaction. Retinal edema is a manifestation of disturbances in the vessel wall. This supports the existence of a relationship between retinal edema and ocular tension.

Ray K. Daily.

Downey, H. R. Unequal tension as a sign in early glaucoma. *Trans. Amer.*

Ophth. Soc., 1945, v. 43, pp. 495-504.

The author calls attention to the importance of unequal tension in the two eyes as a prodromal sign of the "preglaucoma stage" in patients over the age of 40 years. A difference in tension of 4 mm. and more is significant even in the absence of other manifestations of glaucoma. He found this difference in one third of 620 patients with healthy eyes and as frequently before the age of 40 years as after. He reports six cases of definite glaucoma in patients over 40 years of age whose only initial sign of preglaucoma was a difference in tension. C. D. F. Jensen.

Filatov, V. P. Remarks on the technique of the LaGrange-Holt operation. Vestnik Oft., 1946, v. 25, pt. 5, pp. 39-41.

The distinguishing points of the technique are the use of a blunt-pointed keratome to make the incision, after the anterior chamber has been entered with a sharp-pointed keratome; the performance of a prophylactic sclerectomy in anticipated expulsive hemorrhage; and the use of tissue implantation to stimulate the recuperative forces of the organism.

de Grosz, Istvan. Quantitative determination of follicular hormone in eye diseases. Acta Ophth., 1941, v. 19, pt. 2, pp. 134-140.

Thirteen patients with glaucoma and eight with other eye diseases were tested for ovarian inadequacy by the determination of the folliculin content of the urine. The data show a low content of estrogenic substances, and suggest an etiologic relationship between ovarian inadequacy and certain types of glaucoma.

Ray K. Daily.

Hess, Leo. Pathogenesis of glaucoma and "glaucomatous" atrophy of the optic nerve. Arch. of Ophth., 1947, v. 37, March, pp. 324-335.

This paper is one of a series on glaucoma by this author. He here brings out the point that glaucoma may be dependent not only on congenital anomalies of the eye, but may be associated with organic changes in the nervous system.

R. W. Danielson.

Jona, S. Injection of hypertonic glucose in the pre-operative treatment of glaucoma. Rassegna Ital. d'Ottal., 1942, v. 11, March-April, p. 83.

The various salts and solutions which have been employed in the attempt to reduce the intraocular pressure in glaucoma are reviewed. The author doubts their value, except in the preoperative period and when combined with the use of miotics, at this stage. Twenty cases are reported in which 100 c.c. of 50-percent solution of glucose was injected intravenously in a period of ten minutes. In all of these patients there was a moderate reduction of pressure, lasting about two days. There were no inconveniences attendant upon the use of the glucose solution, and its employment before surgery is recommended.

Eugene M. Blake.

Just-Tiscornia, Benito. Intraocular hypertension. Is the cause local or general? Arch. de la Soc. Oft. Hisp. Amer., 1946, v. 6, Oct., pp. 989-998.

This is a report on a patient with general hypertension, with signs of bilateral vascular hypertension in the fundus and raised ocular tension, and with thrombosis of the central retinal vein and glaucomatous excavation in the right eye. The author believes that the local changes in the ocular capil-

laries form the fundamental disturbance, which leads to the increased intraocular pressure, and that the general high blood pressure had no significant influence on the ocular tension.

Lawrence, Arthur. **Glaucoma following herpes.** *M. J. Australia*, 1947, v. 1, Jan. 18, p. 78.

The author presents four brief case reports to draw attention to the fact that glaucoma may follow herpes. Although this is probably secondary glaucoma, the glaucoma may supervene when no sign of iritis can be detected with the slit lamp. F. H. Haessler.

Marin Amat, M. **The pathogenesis of glaucoma.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Oct., pp. 1012-1026.

The author's conception of the pathogenesis of glaucoma is summarized. The rise of intraocular pressure is produced directly by the increased intraocular volume of blood and lymph; obstruction to drainage is secondary. A rapid rise in intraocular contents produces an acute glaucoma; if the increase takes place slowly the glaucomatous process is chronic. The control of the intraocular circulation is under the influence of the sympathetic system, directed autonomically and locally by the small ganglia situated within the ciliary body and the

choroid. Dysfunction of the local regulating mechanism breaks the sympathetic-vagotonic equilibrium which regulates the quantity of blood entering and leaving the eyeball. The result of this disturbance is a vasodilatation and stasis, increased permeability of the capillary endothelium, and intraocular hypertension. The mechanism of the dysfunction may be a primary excitation of the sympathetic followed by an overactivity of the parasympathetic, or a primary parasympathetic excitation. Consequently glaucoma is always predominantly a reaction of the vagus. The clinical implications of this concept are the importance of prophylactic avoidance of all excitation of the sympathetic nervous system and the necessity of acting therapeutically on the nervous plexus in the ciliary body and the root of the iris. The therapeutic goal should be a diminution in the production of intraocular fluids and not promotion of their elimination. The autonomic function of the local sympathetic innervation of the eyeball explains the failure of intervention on the sympathetic cord or its ganglia to reduce ocular tension.

Marlow, Searle B. **The field of vision in chronic glaucoma.** *Trans. Amer. Ophth. Soc.*, 1945, v. 43, pp. 608-625.

The author presents his observations on 50 cases of chronic glaucoma, showing the effect of reduced illumination on the field of vision. He compares his findings with those of earlier observers, emphasizing the conclusions of outstanding investigators in the field of perimetry such as Traquair and Ferree and Rand. He presents 13 perimetric charts which demonstrate the amplification of known or suspected field de-

fects by the use of illumination reduced to an intensity of 0.20 foot candles. He compares these field findings to those with full illumination which ranged from 10 to 40 foot candles in intensity. He concludes that in all perimetric studies the illumination should be measured and recorded.

C. D. F. Jensen.

Norkus, V. N. Elastotonometric investigations with the pressure test in glaucoma. *Vestnik Oft.* 1946, v. 25, pt. 5, pp. 35-39.

The technic of the Dashevski pressure test is as follows: the corneal diameter is reduced to and maintained at 7.9 mm. by pressure with the glass prism of the elastotonometer. Tonometric readings are taken every 10 seconds for two minutes, and the data charted to form a curve. The object of the test is to elucidate the changes that take place in the normal and glaucomatous eye under pressure. The reaction has two phases: a fall in ophthalmotonus, and its restoration. This investigation was concerned with the component factors of ocular tension in the phase of restoration. The eye was subjected to an elastotonometric examination, then subjected to pressure for two minutes, and the elastotonometric examinations were repeated every five minutes until the original level of ocular tension was restored. The tests were made also on the fellow eye that was not subjected to pressure. The data on 22 glaucoma patients show that the eye responds to pressure by a change in the ocular tension and in the coefficient of reaction. These two basic factors change in opposite directions in eyes with a normally functioning regulating mechanism of ocular tension. With a high true intraocular pressure the

changes in the coefficient of reaction are insignificant. The tonometric tension as understood clinically is modified in the presence of high true intraocular pressure. In average and low true intraocular pressure both the pressure and the coefficient of reaction participate in the change. In slight compression of the cornea as is practiced clinically the tonometric reading depends but little on the coefficient of reaction. The changes in the fellow eye were similar to those in the eye that was subjected to pressure.

Parker, F. C. Modified corneal incision with iridodialysis and iridectomy for opening the anterior chamber angle. *Arch. of Ophth.*, 1947, v. 37, March, pp. 277-281.

When one visualizes the point of attack in making the incision for the conventional iridectomy, one cannot but be impressed with the fact that the very area, namely, the angle of the anterior chamber, which should be kept patent, is in serious danger of being subsequently closed by cicatricial contraction or resultant inflammatory changes. An area which should be kept free is traumatized, with the possibility of producing conditions worse than the primary one.

Parker says that the failures in some cases of basal iridectomy might be attributed to the aforementioned location of the conventional incision. In performing an iridectomy, it is almost impossible to cut down to the base of the iris without leaving a stump, however small. Any remnants of iris can still block the angle. He, therefore, places the incision in the clear cornea away from the limbus, where subsequent contraction and other changes would

not in any way interfere with drainage. In addition, the location of the incision facilitates iridodialysis, which is the best procedure for clearing the angle of the anterior chamber.

With a Graefe knife, an incision is made straight through and across the cornea about 3 mm. below the limbus, with the blade of the knife tilted slightly downward to make a beveled cut. The iris is grasped well toward the base and pulled slightly downward with a swaying motion, and is stripped clean from its base high up in the angle. The resulting coloboma can be made of almost any size desirable. The iris is drawn down and out through the incision and cut off first at one extremity of the incision, after it has been pulled away medially from the end of the wound, and then at the opposite end. In replacing the pillars, the tiny stream of an anterior chamber irrigator is employed rather than a spatula, to guard against any possible damage to the capsule of the lens.

Parker does not advocate the performance of this iridodialysis and iridectomy through the modified corneal incision in every case of glaucoma. It should be employed in any eye in which iridectomy might be considered.

R. W. Danielson.

Payne, B. F. **Causes of failure of glaucoma operations.** *Southern Med. Jour.*, 1947, v. 40, Jan., pp. 11-17.

Unsuccessful glaucoma surgery requires that the surgeon, in fairness to his patient, himself, and the profession, investigate the cause for the failure. Histologic study of enucleated eyes in the cases showing poor results is required. The causes for such results in some of the common operations for acute and chronic glaucoma are studied and reported.

Before showing the histologic changes in glaucoma, the microscopic anatomy of the normal globe is briefly reviewed.

Enucleated glaucomatous eyes following unsuccessful iridectomy, iris inclusion operation, cyclodialysis, and trephine showed thinning of the sclera and cornea, changes in the corneal epithelium, congested scleral sulcus and limbus, shallow anterior chamber, anterior peripheral synechias, and atrophy of the iris and ciliary body.

Photographs of sections of enucleated globes after the above named unsuccessful operations clearly illustrate the cause of the failures. In the iridectomy the root of the iris was left behind and the synechias therefore not relieved. The iris inclusion drainage canal was not permanent. Inflammation closed the tract made by the cyclodialysis operation. The trephine failures were due to collapse of the bleb, late infection, and fibrotic closure. (Photomicrographs.) Francis M. Crage.

Rios Sasiain, Manuel. **The mechanism of intraocular hypertension in the light of the polarographic method.** *Arch. de la Soc. Oft. Hisp.-Amer.*, v. 6, 1946, Oct., pp. 999-1011.

Rios subjected the intraocular fluid to an examination by the polarographic method, with the curves recorded photographically. The analytic apparatus and the preparation of the intraocular fluid obtained through posterior sclerotomy or from the anterior chamber is described in detail. The normal aqueous is alkaline, and the polarographic curve indicates the presence of a small protein content in the intraocular fluids. In the hypotensive eye the polarographic curve shows an increase in protein which inhibits the reduction of the ions of cobalt. In the hypertensive

eye the physicochemical equilibrium, which regulates ocular tension is disturbed; neurovegetative instability, endocrine dysfunction, intramural action of histamin, or all of these factors combined, lead to a vascular dilatation and increased capillary permeability. This leads to the diffusion of colloidal proteins, which normally do not pass through vascular walls; the osmotic pressure of the intraocular fluid rises, and the quantity of the intraocular fluid is increased. Chemically the passage of negative ions into the eye raises the alkalinity, and the pH becomes further removed from the isoelectric point.

Rokitskaia, L. B. Investigations of the oculoöcular phenomena by elastotometry. *Vestnik Oft.* 1946, v. 25, pt. 5, pp. 28-31.

This is a further investigation in the elucidation of the mechanism of the binocular response to a monocular stimulus. It is generally regarded as a vasomotor reaction, transmitted to the fellow eye through nervous associations. Dashevsky's investigations with elastotometry revealed that the clinical tonometric data consist of the interaction of two factors: the true intraocular tension and the coefficient of reaction. Elastotometric data determine the reaction coefficient, or the reactive capacity of the eyes. Inasmuch as this coefficient is determined by the elasticity of the vascular wall, a study of the coefficient may give some indication of the part played by the vascular system in the various processes concerned. This study was concerned with the binocular reaction to pressure on the globe with Dashevsky's instrument, which acts on the true intraocular pressure, and to retrobulbar injections of 1:1000 solution of atropine, which

acts directly on the vessel wall and thus indirectly on the coefficient of reaction. The graphically reported data show that in normal eyes the effect of pressure on the true intraocular tension and on the coefficient of reaction runs parallel in both eyes, and that pressure on one eye elicits a binocular response which is less marked and appears somewhat later in the fellow eye. In eyes with glaucoma the reactions were variable and inconstant, owing probably, to the extreme lability of the nervous mechanism of such eyes. Retrobulbar injections of atropine produced definite changes in the coefficient of reaction in most cases with but little effect on the true ocular tension and the same response was found in the fellow eye. These findings thus cast doubt on the conception of oculoöcular reactions as purely vasomotor phenomena.

Sadikova, V. C. Results of cyclodialysis. *Vestnik Oft.*, 1946, v. 25, pt. 5, pp. 42-45.

A review of the literature, and an analysis of 100 operations on 93 patients is reported. Among these were 7 cases of compensated glaucoma, 87 of uncompensated, 2 of absolute, 1 of acute glaucoma, and 3 of juvenile. There was a shallow anterior chamber in 70 cases, moderate in 21, and deep in nine. There was postoperative iridocyclitis in six. The criteria in this investigation were the visual acuity, peripheral fields, and ocular tension. The tabulated data show an improvement in visual acuity in patients with poor vision. In patients with good vision there was a reduction in visual acuity in 25 percent attributed to the changes brought about by the surgical intervention, such as pigment in the anterior chamber, folds and detachment of

Descemet's membrane, and refractive changes. In 86 cases ocular tension was gradually reduced, as were the oscillations in ocular tension. The visual field increased in 25 patients and became contracted further in 11. (4 tables.)

Samoilov, A. I. **New pathways in the study of glaucoma.** *Vestnik Oft.*, 1946, v. 25, pt. 5, pp. 3-7.

The theories on the pathogenesis of glaucoma are reviewed. Samoilov is convinced that the basic process in the initial stage of glaucoma is an edema of the eyeball, localized predominantly in the retina, and has specific characteristics. Among these is the typical reaction of the glaucomatous eye to pilocarpine and adrenaline. Adrenalin has a pronounced pupillomotor effect but no effect on the retinal edema; pilocarpine produces less miosis in the glaucomatous eye than in the normal, but produces a significant diminution in the retinal edema. If persistent the retinal edema gradually passes into an atrophy of the optic nerve. This process is not specific for glaucoma. The fact that the visual acuity continues to deteriorate in many cases in which the tension has become normal after surgery is evidence to Samoilov that the ocular tension is not the cause of the visual deterioration.

Samoilov, A. I., and Briantseva, M. K. **Campimetric test in darkness in the diagnosis of prodromal glaucoma.** *Vestnik Oft.*, 1946, v. 25, pt. 5, pp. 12-17.

The most sensitive test for prodromal glaucoma is the demonstration of the presence of retinal edema through an enlargement of the blind spot. This demonstration is possible under conditions of dark adaptation before it is

demonstrable in the light adapted eye. One has the patient remain in a dark room for one hour, takes the adaptation curve to verify the state of adaptation, and then outlines the blind spot, using a feeble light for fixation, and a small red light for the test object. After a return to normal illumination the blind spot soon resumes its normal size. One of the interesting observations made in the course of this investigation, was that frequently the normal eye of a glaucomatous patient showed an enlarged blind spot in dark adaptation. Of nine eyes found normal ophthalmoscopically, tonometrically, and functionally only three had a normal size blind spot when dark adapted. (Adaptation curves, blind spots.) Ray K. Daily.

Sugar, H. S. **Acute glaucoma: a follow-up study.** *Amer. Jour. Ophth.*, 1947, v. 30, April, pp. 451-468. (1 chart, 3 tables, 8 references.)

Vanýsek, Jan. **The problems of glaucoma.** *Brit. Jour. Ophth.*, 1946, v. 30, Dec., pp. 742-748.

The author believes that glaucoma may be an expression of tissue edema in the eye; this is either an ordinary edema or more probably an allergic type. The ordinary swelling may be either inflammatory, as in iritis or iridocyclitis, or cardiac edema, as in thrombosis of the central vein of the retina. The allergic edema is brought about by an imbalance in opposing divisions of the vegetative nervous system. The frequency with which glaucoma is precipitated by excitement that upsets balance between the sympathetic and the parasympathetic functions is cited as evidence of this. A further evidence is given the fact that tension is higher during the night when the sympathetic system is more active, and less ele-

vated during the day when the parasympathetics hold sway. The author acknowledges there is no proof of this hypothesis, but feels that much more thought should be given it.

Morris Kaplan.

Vidal, F., and Malbrán, J. L. **Chronic primary glaucoma and differential white cell count.** *Arch. de Oft. de Buenos Aires*, 1946, v. 21, Jan.-March, p. 58.

The differential white cell count in the blood of 21 patients with chronic primary glaucoma and 14 with secondary glaucoma was found to be normal. (Bibliography.) Plinio Montalván.

Vintserevich, M. A. **Elastotonometric analysis of the action of miotics in glaucoma.** *Vestnik Oft.*, 1946, v. 25, pt. 5, pp. 32-35.

The material for this investigation comprises 67 glaucoma patients tested for the effect of miotics, and 200 glaucoma patients examined without consideration of the action of miotics. The elastotonometric data show a variable response to miotics owing, probably, to the extreme lability of the nervous system in glaucoma. Varying and sometimes contradictory responses may follow the same stimulus. Nevertheless the data reveal a number of interesting phenomena. They show that the lower the true ocular tension is, the higher is the coefficient of reaction. A low coefficient of reaction was found in eyes with absolute glaucoma with a high true ocular tension. In compensated glaucoma the coefficient is higher. An elastotonometric examination furnishes three data: a tonometric datum which is obtained by measuring the pressure necessary to deform the cornea to produce a plane surface 4.8 and 7.9 mm. in diameter; and the true intraocular

pressure and the reaction coefficient, which are calculated. Under the influence of miotics the tonometric data remain unaltered, and the true ocular tension and the reaction coefficient undergo a change usually in opposite directions. In lower tension the coefficient rises and vice versa. In a few cases the two components change in the same direction. No significant difference was found in varying the concentration of the miotics. In the light of elastotonometric data our conception of the action of miotics needs revision. (Elastotonometric curves.)

Ray K. Daily.

Wexler, D., and Kornzweig, A. **Buphthalmos in a six month premature infant.** *Arch. of Ophth.*, 1947, v. 37, March, pp. 318-323.

Infantile glaucoma, or buphthalmos, has been discovered occasionally in newborn infants at term. The present case is of special interest because it affords an opportunity to study congenital glaucoma in microscopic section at an earlier stage than has hitherto been possible. On section, it was found to belong to the small group of cases of buphthalmos characterized by absence of Schlemm's canal, complete anterior iris synechias and very shallow or absent anterior chamber. These anatomic features were striking in comparison with the deep anterior chamber and hydrophthalmos more commonly found in congenital glaucoma.

Of clinical interest in this premature infant with buphthalmos is the presence of a hereditary tendency to familial congenital glaucoma, and of consanguinity of the grandparents. Detailed measurements of the eye are compared to those of a normal six-month fetus.

CRYSTALLINE LENS

Arruga, H. The simultaneous detachment of the choroid and the retina after a cataract operation. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 119-125.

In 1868, H. Knapp described the first case of detachment of the choroid in an enucleated eye recently operated upon for cataract. At the time of the enucleation, it was believed that the patient had developed a sarcoma of the choroid. In the presence of detachment of the choroid following cataract extraction or trephining the patient is usually not aware of any disturbance but if the detachment is very large he may notice the contraction of the visual field with an area of blindness having a convexity directed toward the center. The retraction of the visual field goes through a period of progression and regression which may last days or weeks. With rare exceptions there is complete restitution. The fundus may show one or more raised areas resembling a tumor of the choroid. The mass is not opaque to transillumination and shows a hard reddish reflex. The rest of the fundus is normal. The anterior chamber is almost always very shallow due to the lack of healing of the operative wound. Predisposing causes of the detachment are considered to be old age, hypertension, and dyscrasias, especially diabetes. In a few cases there is an associated detachment of the retina which carries the same favorable prognosis as the choroidal detachment. It is believed that the detachment is probably due to congestion *ex vacuo* which produces an exudate from the vascular membrane itself. The retinal detachment is thought to have the same cause. The author has examined 242 pa-

tients postoperatively. He observed detachment of the choroid in 9; in 3 of the 9 there was also a contiguous detachment of the retina. He concludes that the above figures indicate the relative frequency of choroidal detachment and associated retinal detachment resulting from intraocular surgery. (4 illustrations.) J. Wesley McKinney.

Bettman, J. W. Production of cataracts in chicks with dinitrophenol. *Arch. of Ophth.*, 1946, v. 36, Dec., pp. 674-676.

It has not been found possible to experimentally produce cataracts in mammals by the ingestion of dinitrophenol, although this has been done in young chicks and ducks. The author produced cataracts in 3½-weeks-old pullets by placing them on a diet containing 0.25 percent 2:4 dinitrophenol. Within seven hours definite lenticular opacities were noted in each eye of all the chicks. The opacities were limited to the anterior and posterior subcapsular regions. The cataracts regressed to a considerable degree even while the drug was still being administered. White mice and congenitally obese yellow mice failed to develop cataracts under the same conditions.

Decker, P. H. A method of closing the cataract incision by combining a corneoscleral suture and a large sliding

conjunctival flap. *Trans. Amer. Acad. Ophth.*, 1947, Jan.-Feb., pp. 210-213.

The author successfully uses the following technique to secure adequate approximation and sealing of the incision in 125 operations. The conjunctiva is circumcised as in enucleation over the upper three fifths of the limbus and undermined sufficiently to prevent tension. With a 6-0 black silk suture, a horizontal corneoscleral mattress suture is inserted and tied after the completion of the operation. The conjunctival flap is then brought down over the upper half of the cornea and held in place with two sutures. These sutures are removed on the fourth day and the corneoscleral suture on the twelfth.

Chas. A. Bahn.

Disler, N. N. Three cases of injury of the lens without subsequent cataract formation. *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 40-41.

In the course of development of traumatic cataracts, Disler observed peripheral, subcapsular, round or elongated vacuoles not connected with the perforation in the lens capsule. They are the first sign of an impending opacification of the area; they indicate a progressive hydration of the tissue and inescapable opacification. Gradually the groups of vacuoles and the number in each group increases. They become confluent and form a continually extending ring in the lenticular periphery, which joins other areas of hydration and opacification. Disler also had under observation three injuries of the lens, in which these peripheral opacities were absent. All three remained without the development of cataract for the three years. One lens had a glass splinter partially imbedded in it. The other lens was perforated by a piece of copper

which lodged in the vitreous; the third lens contained a fine transparent foreign body in its superior inner quadrant. Disler infers that in trauma of the lens the peripheral vacuoles are of prognostic significance.

Ray K. Daily.

Galois, A. Cataract extraction with keratome incision. *Ann. d'Ocul.*, 1946, v. 179, Sept., pp. 492-497.

The use of a keratome instead of a Graefe knife for cataract extraction is advised to avoid increased delayed healing and iris prolapse. A keratome incision is suggested which is so large that enlargement with scissors is not necessary. The technique described has been used by the author in 250 cases during a period of eight years. This is essentially the technique suggested by Duverger and Velter. In operating on the left eye a suture through the external rectus is used for fixation; on the right eye, a suture in the internal rectus. The conjunctiva is dissected down to the limbus. With a large keratome a limbal incision is made several mm. to the left of the vertical meridian. The keratome is passed as far into the anterior chamber as possible and in its withdrawal the section is enlarged by means of the lateral cutting edge on one side. A total iridectomy is performed. If the lens capsule is very tense due to lens intumescence a very small puncture with the cystotome is made in the capsule near the equator preliminary to intracapsular extraction. Nasal and temporal scleral corneal sutures are used.

Chas. A. Bahn.

Henkes, H. E. On the distribution of glutathione and vitamin C in the lens and cornea. *Ophthalmologica*, 1946, v. 112, Sept., pp. 113-128. (See Section 6, Cornea and sclera.)

Maestro, Tullio. The ascorbic acid content of the cornea. *Rassegna Ital. d'Ottal.*, 1941, v. 10, Sept.-Oct., pp. 487-500.

Eighteen white rats were fed upon a diet deficient in vitamin A. The oxidation of the fatty acids and their esters was studied and the results were related to the changes in human cataractous lenses. The respiration of the opaque human lens is raised by the fatty acid esters. The present researches confirm the finding of this oxidation in the lens, which has been previously demonstrated in many other tissues. Butyric acid was shown to be especially active upon the cataractous lens fibers. Eugene M. Blake.

Nicolato, A. Two hundred cases of intracapsular cataract extraction. *Rassegna Ital. d'Ottal.*, 1942, v. 11, Jan.-Feb., p. 3.

Intracapsular and extracapsular extraction of cataract are compared. The necessity for careful study of each eye is stressed, so that the attempt to remove the cataract in its capsule will not fail. The author feels that the intracapsular method gives better results in every way and that late complications are less frequent than with the classical procedure. Eugene M. Blake.

Villa-Coro, A. Optic nerve atrophy after a cataract operation. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Sept., pp. 901-904.

The importance of this work is to suggest the incidence of optic nerve atrophy after a cataract operation when the atrophy has no other cause. After 5,000 cataract operations the author found that 10 of these patients developed optic nerve atrophy.

RETINA AND VITREOUS

Arruga, H. The simultaneous detachment of the choroid and the retina after a cataract operation. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 119-125. (See Section 9, Crystal-line lens.)

Bailliant, P. Circulation of the retina and general medicine. *Wien. Klin. Wchnsch.*, 1946, v. 58, June, pp. 332-337.

The observation of the retinal circulation is becoming more and more important for specialists and for general physicians. The oculist sees in the retinal vessels the basis for the retinal nutrition, the neurologist pictures in them the state of the cerebral vessels, the physiologist and general physician finds in them clues to the behavior of the peripheral circulation which is responsible for the life of the cell and influences the general blood pressure. We are able to measure the pressure of retinal arteries and veins, can measure their thickness, can observe the circulation of the blood corpuscles, can estimate the elasticity of their walls and can even photograph them. Because strong drugs changed the caliber of the vessels only little and the existence of vasomotor nerves in both cerebral and retinal vessels has been denied, it was assumed that the general blood pressure was the responsible factor for the pressure in these organs. Stimulation and excision of the nervous elements of the carotid sinus showed that the pressure changes in the retinal arteries do not correspond to the general blood pressure. The caliber of the retinal vessels is no longer important. In its place we emphasize the local pressure measured by the dynamometer. The circu-

lation in a given area varies according to its activity at any given time. The exchange of the substances necessary for the metabolism of the cells is variable and is regulated by changes in the tonus and not by changes in the caliber of the vessel wall. If the tonus increases, the blood pressure increases in this area. A spasm of the peripheral vessel is not normal and is the exception. If the tonus of an artery decreases, the pressure does not only sink in the artery, but in the capillaries and veins of the area as well. Increased peripheral pressure decreases the blood supply of the area through increased resistance. The blood pressure, as it is measured consists of the true pressure plus the tension of the blood vessel wall. The latter is relatively insignificant in an artery with a thin muscular wall, but is significant in the retinal arteries. It is the tonus of the wall which keeps up the circulatory pressure and counteracts the effect of gravity, it is this tonus which varies with excitement, which may cause higher or lower local pressure in cases of generalized hypertension or which may slow down the local circulation to complete interruption. Retinal hemorrhages may or may not be associated with general hypertension. Hemorrhages may be an expression of localized hypotony as in pernicious anemia. It is too often forgotten that the blood vessels themselves are composed of cells and that they themselves undergo pathologic changes. At first these diseased cells only cause a disturbance of the normal metabolic interchange, later they may disintegrate and permit the exit of blood from the vessel. A degeneration of the cells of the whole vessel wall leads to obliteration. In the case of end arteries like those in the brain and in the retina such obliteration means sudden func-

tional death, which, unless the obliteration is quickly relieved, becomes permanent. Embolism in the retinal arteries and venous thrombosis and their consequences in the retina are also described. Max Hirschfelder.

Baquis, Mario. Retinal hemorrhages from strain. *Rassegna Ital. d'Ottal.*, 1941, v. 10, July-Aug., pp. 417-437.

Baquis defines overwork, or strain as an activity of a working individual surpassing physiological limits in intensity or duration. The strain may be physical or psychic, muscular or mental. Three cases of sudden loss of vision due to hemorrhages of the retina which followed excessive muscular effort are described. E. M. Blake.

De Leonibus, F. The ability of the normal lens to survive the oxidation of some amino acids. *Rassegna Ital. d'Ottal.*, 1941, v. 10, Nov.-Dec., pp. 547-556.

De Leonibus reports briefly upon our present understanding of the metabolism of the amino acids, with particular regard to the researches upon the influence of these substances upon the retina. The method of Warburg was further employed to study the relation of the amino acids to the lens in concentrations of M/100, at pH of 7.2. The results were not conclusive. Certain of the amino acids increased the respiration of the lens, and others decreased this property. Apparently the amino acids play a minor role in the metabolism of the lens. Eugene M. Blake.

Ershkovich, I. G. Tissue therapy in traumatic changes of the vitreous during the World War. *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 16-20.

This study is based on 20 cases of vitreous opacity following war injuries,

14 of which were perforating and six contusions. In two eyes intraocular foreign bodies were extracted, and six contained nonmagnetic foreign bodies. Half of the injured had additional injuries of the face, chest, and extremities. In eleven patients there was a dense organized exudate encapsulating a foreign body and in five of them the retina was detached. In seven there was a hemophthalmos, and in two retinitis proliferans. Of the twenty patients three had only one eye, and one had both eyes injured. Tissue therapy was instituted one to nine months after the injury. In 10 patients tissue therapy was combined with osmotherapy and autohemotherapy. There was improvement in 18. The favorable effect was observed in six eyes containing an intraocular foreign body, and in six with retinal detachment. The author urges a trial of this therapy in eyes regarded as hopeless. Ray K. Daily.

Ferrié, J. Macular lesions of degenerative appearance and their relation to tuberculosis. *Ophthalmologica*, 1946, v. 112, Sept., pp. 135-148.

For a number of years the author has been especially interested in the distinction between inflammatory and degenerative macular lesions. In 1941, together with Lafont, he presented before the ophthalmological Congress of Southern France (Montpellier, June, 1941) a study of Stargardt's disease associated with a neurologic syndrome of the order of Friedreich's ataxia. Of this combination of hereditary macular and neurologic disease, Ferrié now reports two cases (father and daughter) with typical macular lesions of the Stargardt type but definite evidence of congenital syphilis. Ferrié then describes and depicts in color a bilateral chronic macular disease of typically degenerative ap-

pearance in four adults with definite evidence of active or arrested pulmonary tuberculosis. The author's ophthalmoscopic criteria of degenerative macular disease appear to be the same as those used in English-speaking countries. Rather cautiously and without any definite evidence other than the coexistence of the two conditions he suggests a tuberculous etiology of macular lesions of degenerative appearance in definitely tuberculous adults.

Peter C. Kronfield.

Givner, I., and Bruger, M. Associated systemic factors in retinitis pigmentosa. *Arch. of Ophth.*, 1947, v. 37, March, pp. 261-267.

This study was prompted by two cases of retinitis pigmentosa with unusual associated conditions. An attempt to determine whether these additional factors were constantly present led to laboratory investigations, of which this paper is a preliminary report. The present series includes 14 patients.

The unusual feature of one case was a spinal fluid pressure of 300 mm. of water. In the other patient the spinal fluid was under normal pressure, but the total protein measured 194 mg. per hundred c.c. (normal 15 to 40 mg.) and the chlorides 1,195 mg. per hundred c.c. (normal 700 to 750 mg.). In addition, the basal metabolic rate was 17 percent below the average and creatinuria was present.

No abnormalities in pulse rate, blood pressure or temperature were observed in 14 patients with retinitis pigmentosa. The serum cholesterol was within normal limits. The basal metabolic rate was within or below normal limits. Eleven patients had creatinuria. Spinal fluid pressure and total protein content of the spinal fluid was definitely

increased. Hepatic damage was not demonstrable. The fasting ascorbic acid content of the plasma was reduced in seven of nine patients on whom this determination was carried out. Vitamin A studies on the serum of seven patients gave normal values.

In 11 patients pupillographic studies showed tonohaptic reactions and other evidences of diencephalic disorders. Tests failed to reveal any measurable impairment in renal function in 13 patients. Physical examination, including neurologic studies, gave essentially normal findings except for the high incidence of high-arched palate and nerve deafness. R. W. Danielson.

Goldfeld, R. G. Tissue therapy of fundus changes with hole in the macula due to contusions. *Vestnik Oft.* 1946, v. 25, pt. 1, pp. 24-26.

Three of four eyes with traumatic hole in the macula treated by tissue therapy were improved. The improvement is attributed to the absorption of edema and exudate in the parimacular area. It is suggested that all patients with such injury be given the benefit of this therapy. Ray K. Daily.

Hallum, Alton V. Retinal arterioles in the hypertension of pregnancy. *Trans. Amer. Ophth. Soc.*, 1945, v. 43, pp. 585-607.

Hallum offers a classification of retinal arteriolar spasm in toxemia of pregnancy, based on the degree of retinal arteriolar spasm. He considers its evaluation a distinct aid in determining if, and when, pregnancy should be terminated. C. D. F. Jensen.

Jordano Barea, Jose. Localization of the tears in an operation for detached retina. Thermoluminous caliper meth-

od. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, 5, Dec., pp. 1130-1136.

The instrument consists of an ophthalmoscope to which is added a metallic arm. Into this is placed a long curved electrode. Thus, one has a caliper whose intraocular arm is the light projected by the ophthalmoscope and the extraocular arm is formed by the electrode. The electrode marks the place of the tear on the sclera. (6 illustrations.) J. Wesley McKinney.

Jordano Barea, Jose. Thermoluminous caliper method for localization of the tears in detached retina. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 203-208.

In a previous article published in this journal in December, 1945, the author describes his method of the thermoluminous caliper. Now he gives further advice about its use.

J. Wesley McKinney.

Maestro, Tullio. Changes in the retinal arterial pressure in a patient suffering from a paralysis of the cervical sympathetic nerve. *Riv. Oto-Neuro-Oft.*, 1942, v. 19, Nov.-Dec., pp. 413-421.

A 30-year-old married woman developed a typical Claude Bernard-Horner syndrome two days after an injection had been given into the thyroid gland. The intraocular pressure remained equal in both eyes during four months, but the diastolic arterial pressure stayed higher in the eye on the side of the sympathetic lesion for about two months. The differences in pressure varied from 5 to 10 millimeters when measured with the ophthalmodynamometer of Bailliart. The ptosis, miosis, and enophthalmos did not disappear when the diastolic arterial pressure became equal in both eyes. During

this time, no changes in the retinal vessels could be seen. K. W. Ascher.

Niven, C., Jr., Washburn, M., and Sperling, G. Growth retardation and corneal vascularization with tyrosine and phenylalanine in a purified diet. *Proc. Soc. Exper. Biol. and Med.*, 1946, v. 63, Oct., pp. 106-108.

The addition of 1 percent DL-phenylalanine and 1 percent L (-) tyrosine to a purified diet containing 10 percent casein produced growth retardation and external lesions. Phenylalanine is converted to tyrosine in the animal and so may add to the effect of the tyrosine. The addition of relatively large amounts of nicotinic acid or L (-) tryptophane will appreciably alleviate the deleterious effects of these amino acids. Theodore M. Shapira.

Pereyra, Lorenzo. Coats' disease. *Riv. di Oftalm.*, 1946, v. 1, July-Aug., pp. 489-509.

The author reports a clinical study of two cases of bilateral Coats' disease and a histologic study of one eye that was enucleated because of decompensated glaucoma. Vascular, degenerative, and proliferative lesions were encountered histologically. The most impressive vascular lesion consisted of an enormous dilatation of the choroidal network; the thickness of the choroid was five times that of the normal membrane. The retinal vessels, on the other hand, were constricted, even partly occluded, and showed thickening of their walls. Degenerative changes were found in the retina, particularly in those layers adjacent to the exudate which was found between the choroid and the retina and which, on chemical examination, showed a high globulin content. Proliferative lesions found in

the retina faintly resembled a glioma which, however, was excluded by the absence of atypical cells and by the relative preservation of the retinal cytoarchitecture. The transudate located between the choroid and the retina was believed to originate from the enormously dilated and permeable choroidal vessels; the essence of this lesion was assumed to be a malformation, an angiomatosis belonging to the group of hamartomas. A hypoplasia of the choroidal vessel walls seemed to be the primary cause of the dilatation of these vessels and of the enormous transudation which interfered with the normal nutrition of the retinal tissue. The remissions which were observed in many eyes affected by Coats' disease as well in those described by the author, may well be explained by temporary resorption of a part of this transudate. A relationship to Hippel-Lindau disease is mentioned. (Bibliography, 10 photomicrographs.) K. W. Ascher.

Pokrovsky, A. I. The pathogenesis and therapy of retinal detachment of tuberculous origin. *Vestnik Oft.*, 1946, v. 25, pt. 6, pp. 17-20.

The clinical history of a patient is reported to show that in the presence of tuberculous chorioretinitis a slight trauma may lead to retinal detachment with a hole which simulates idiopathic detachment. The presence of a retinal tear is an indication for diathermy coagulation, but a favorable surgical result should not lead to the neglect of general therapy including tuberculin therapy. Ray K. Daily.

Samoilov, A. I. Retinal edema in tuberculous diseases of the anterior ocular segment. *Vestnik Oft.*, 1946, v. 25, pt. 6, pp. 20-25.

Case reports illustrate the occurrence of retinal edema complicating anterior uveal tuberculosis without choroidal involvement. The low visual acuity sometimes found in anterior uveitis may be due to the retinal edema. Calcium iontophoresis is valuable diagnostically in diminishing the edema, and consequently the size of the scotoma. Calcium iontophoresis is a valuable desensitizing measure, and also a therapeutic procedure for diminishing the edema and restoring function. Further investigations will show whether the retinal edema represents a specific tuberculous process in anterior uveitis, or may occur in similar processes of other etiology. Ray K. Daily.

Sandomirsky, L. A case of Purtscher's retinopathy. *Vestnik Oft.*, 1946, v. 25, pt. 4, pp. 44-45.

A soldier was struck in the occipital region with a heavy piece of wood, and the following morning he noticed loss of vision in the left eye, which was found to be due to Purtscher's retinopathy. The loss of vision was permanent. The literature on this rare condition is reviewed. (Illustration.)

Ray K. Daily.

Skorodinskaja, V. V. The treatment of retinitis pigmentosa with extract of leaves of aloes. *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 9-12.

This clinical study done at Tashkent comprises 12 cases. Nine adults and three children were studied. Eight of the 12 patients had impairment of hearing. They had been treated with favorable results with intramuscular injections of cod-liver oil. During the war this was not available and the extract of leaves of aloes was given in 1 to 2 c.c. doses, daily or every other day, for 45 injections. In some cases tissue im-

plantation was also done. Extension of the visual field, increased visual acuity, or diminished hemeralopia were considered signs of improvement. Detailed reports show that improvement appears after the eighth to the thirteenth injection. The first sign of improvement was an extension of the visual field, visual acuity rose next, and adaptation was the last function to improve. The courses of treatment were repeated every two to three months, because at the end of the third month visual acuity fell again. In children the extract can be administered in the form of small enemas. The period of observation varied between 7 and 18 months. Whether the process could be permanently arrested cannot be determined from this study, but it is obvious that the effect of therapy is favorable. It manifests itself not only in the ocular function, but also in the general condition of the patient. Ray K. Daily.

Streiff, E. B., and Monnier, M. Influence of vestibular irritation on retinal arterial pressure and on general blood pressure. *Riv. Oto-Neuro-Oft.*, 1942, v. 19, March-April, pp. 81-100.

The authors studied the changes produced by irrigation of the vestibulum of anesthetized rabbits and cats. Water at 45 to 50 and at 5 to 18 degrees centigrade was used, and the arterial pressure in the retina was measured. Another series of experiments was performed on cats with previously interrupted brain stem and cervical sympathetic tracts. Galvanic irritation of the bulla ossea was also used. Clinical observations were correlated with these animal experiments. During vestibular irritation a drop in both general and retinal arterial blood pressure was noted; after cessation of the irrita-

tion, the general blood pressure returned to normal and the retinal arterial pressure surpassed its original values ("hypertensive reaction"). This hypertensive reaction was not observed in animals in which the cervical sympathetic or the pontine tracts had been destroyed. (Extensive bibliography; schematic drawings of high didactic value).

K. W. Ascher.

Weeker, L. Adhesive episcleral reaction in the operative treatment of retinal detachment. *Brit. Jour. Ophth.*, 1946, v. 30, Dec., pp. 715-722.

Ordinary operative methods of treatment of detached retina aim primarily at the formation of an adhesive chorioiditis at the site of the retinal tear. In studying the healing of knife punctures through the bulbar walls in rabbits, it was seen that the newly formed episcleral connective tissue penetrated through the sclera and became attached very firmly to the retina. The same condition prevailed in human eyes similarly penetrated before removal for various causes. The author believes that this adhesive episcleral reaction is essential for the permanent reattachment of the retina. It takes place irrespective of the method of perforation.

He describes an operation procedure that gives a satisfactory adhesive episcleral reaction. First the nonperforating diathermic electrode is applied to the sclera in the area of the tear. This serves to promote the usual adhesive choroiditis. Then a diathermy needle 2 mm. by 0.15 mm. with the least amount of current for easy perforation is used to puncture the tissues from 3 to 20 times. Lastly the sclera and choroid are punctured with an actual cautery point for the evacuation of subretinal fluid. (4 figures.)

OPTIC NERVE AND TOXIC AMBLYOPIAS

Bushmich, D. G., and Getman, V. P. Tissue therapy in optic atrophy. *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 20-24.

The introduction of methyl alcohol into the occupied areas by the German occupying forces led to a number of cases of methyl alcohol poisoning and optic atrophy. This clinical experience comprised 25 patients with an optic atrophy of from two months to two years duration. The majority of these patients had been treated without significant effect by means of blood transfusions, strychnine injections, and intravenous injections of sodium iodide. Because of the advanced stage of the process these patients were given several courses of combined tissue therapy in the form of implantation of preserved skin and placenta, intramuscular injections of cod-liver oil, subcutaneous injections of extracts of preserved leaves of aloes and placenta. The visual acuity and visual field for form and colors were checked every other day. Visual acuity improved in 17 cases, and the visual field in 14. In six patients with no light perception and in one with imperfect light projection there was no improvement. The period of observation extended from 4 to 18 months, and during this time the improvement was stable. While the improvement consisted only in several hundredths of visual acuity, the results are nevertheless considered encouraging because of the gravity of the process and because former therapy was ineffective. The better results reported by Bushmich in the treatment of traumatic optic atrophy suggest that perhaps early treatment before irreversible pathologic processes had time to develop might have been more effective.

tive. It is advocated that this form of therapy be administered within the first few days after the poisoning, with the object of stimulating the fermentation capacity of the tissues and eliminating the action of products of decomposition of methyl alcohol on the optic nerve.

Casari, G. F. Vitamin A test in the differential diagnosis of optic atrophy and chronic glaucoma simplex without manifest hypertension. *Rassegna Ital. d'Ottal.*, 1946, v. 15, July-Aug., pp. 305-314.

Casari made carefully controlled tests of the light minimum, the light difference, and color perception in cases of optic atrophy and probable early glaucoma. The patients were then given 600,000 units of vitamin A in oil orally. Patients affected with optic atrophy and with chronic glaucoma simplex present a definite disturbance of the light sense, with manifest hemeralopia. The use of massive doses of vitamin A improves the light sense in simple atrophy but has no affect in glaucoma, and therefore, may be used to differentiate between the two conditions.

Maestro, Tullio. Choked disc "ex vacuo." *Riv. Oto-Neuro-Oft.*, 1943, v. 20, March-April, pp. 112-134.

A 12-year-old girl developed a unilateral choked disc in an eye with a severe tuberculous keratitis. When, after three months, the cornea had

healed and intraocular pressure had returned to normal, the disc regained a normal appearance. The mechanism of the papilledema and related conditions is extensively discussed and the conclusion is reached that three factors contribute to the development of the choked disc. An increase of the intra-venous pressure is the most important, and slowing of the venous flow and interference with the lymph return are the contributory causes. (Bibliography, 2 figures.)

K. W. Ascher.

Sanchez Martinez, L. The tumors of the frontal lobe. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 170-189.

Two cases of frontal lobe tumor are reported. The first had simple optic atrophy in the left eye with marked concentric contraction of the peripheral field, absolute central scotoma and achromatopsia and in the right eye papilledema of six diopters, narrow arteries, large and tortuous veins, slight contraction of the peripheral field and enlargement of the blind spot. A diagnosis of a tumor of the left frontal lobe was made. The second case was one of tumor of the right frontal lobe. There was bilateral papilledema of five or six diopters, the disc was covered with exudate and hemorrhagic dots, the arteries were narrow and the veins large and tortuous. There was slight concentric contraction of the peripheral fields with enlargement of both blind spots. (Illustrations.)

VISUAL TRACTS AND CENTERS

Brockman, N. W., and Van Hagen, K. O. Denial of own blindness (Anton's syndrome). *Bull. Los Angeles Neurol. Soc.*, 1946, v. 11, Sept.-Dec., pp. 178-180.

Patients who deny blindness usually present considerable intellectual deterioration, impairment of memory, disorientation and confabulation. There is complete blindness apparently due to bilateral involvement of the optic lobes or optic radiations. The pathogenesis of this condition is incompletely understood, but appears to be due to a disturbance in the to and fro circuits between the thalamus and the occipital cortex. Two typical cases are reported.

O. H. Ellis.

Caramazza, F. **Meningioma of the tuberculum sellae.** Riv. Oto-Neuro-Oft., 1943, v. 20, Jan.-Feb., pp. 1-18.

A woman, 32 years of age, noticed fogged vision in her left eye in 1939. Her right pupil was slightly larger. Both discs were pale. Disc borders, retinal vessels, and retinal vascular pressure were normal. Vision of the right eye was 10/10. The left eye counted fingers at 30 centimeters only. Visual field examination revealed a right homonymous hemianopsia, no central scotoma on the right field and a definite left central scotoma. Neurologic and laboratory findings were negative; radiography of the skull revealed anteroposterior enlargement of the sella (X-ray photographs), small anterior and posterior clinoids, normal optic canals, and no signs of increased intracranial pressure. Encephalographic findings were negative. Surgery revealed the presence of a meningioma of the tuberculum sellae, flattening of the compressed left optic nerve and discoloration of the right optic nerve. The right eye retained vision of 10/10. The difficulties of the preoperative diagnosis were due to the lack of encephalographic findings typical for the Cushing meningiomas.

K. W. Ascher.

Colaciuri, Vittorio. **Neurochiasmatitis of vascular and of meningeal origin.** Riv. Oto-Neuro-Oft., 1942, v. 19, Nov.-Dec., pp. 357-381.

This is a histologic study of the inflammatory lesions in and about the optic chiasma of eight patients, suffering from syphilitic (5 cases), tuberculous, and an unknown meningocerebral disease and disseminated sclerosis. The syphilitic lesions showed increased interstitial connective tissue, hyperplasia, and new formation of blood vessels, scanty myelin degeneration and rarefaction of the axis cylinders. Few changes were seen in the glia and in the leptomeninges. These latter structures showed definite alterations in the three patients with nonsyphilitic disease; myelin degeneration and axis cylinder rarefaction were also present. The author suggests means to differentiate neurochiasmatitis of vascular origin from meningeal. (12 photomicrographs; 11 references.)

K. W. Ascher.

Frantz, Russell, and Vogel, P. J. **Visual hallucinations as localizing manifestations of lesions of the temporal and occipital lobes.** Bull. Los Angeles Neurol. Soc., 1946, v. 11, Sept.-Dec., pp. 135-144.

The authors present two cases in which visual hallucinations, one of color and the other of highly organized animate objects (on one occasion colored), were present and seemed to have a localizing value. A review of the recent literature calls attention to widely divergent opinions as to the significance of visual hallucinations in localization.

O. H. Ellis.

Fortunato, Francesco. **Ocular signs produced by cysts of the pouch of**

Rathke. *Riv. Oto-Neuro-Oft.*, 1943, v. 20, March-April, pp. 69-93.

One year after a marked diminution of his sexual functions, a 36-year-old man noticed visual disturbances and general exhaustion. In the course of the next two years he gained 11 kilograms in weight, suffered from headaches, pain in his neck, paracusis, flickering in his left eye, weakness of his legs, incontinence, vomiting, and one attack of generalized convulsions. Neurological findings were normal except for a slight diminution of his olfactory and gustatory senses. Vision was 5/60 in the left and 9/10 in the right eye; the visual field of the left eye was constricted for colors in its lower half, and showed a large (20 degrees) central scotoma, the field of the right eye had a relative central scotoma for colors. The left disc was surrounded by edema and its temporal half was pale; the right disc showed an incipient papilledema. The sella was enlarged and its borders markedly destroyed. A craniopharyngioma was diagnosed, and partly removed. After the operation, the atrophy of the optic nerves proceeded and vision deteriorated. A Cushing decompression operation was performed two months after the first intervention. The final vision was 4/60 in the right eye, and amaurosis in the left eye. (6 figures, bibliography.) K. W. Ascher.

Pedico, O. Chronic serous meningitis. *Rassegna Ital. d'Ottal.*, 1946, v. 15, July-Aug., pp. 319-333.

Pedico emphasizes that chronic serous meningitis is frequently confused with brain tumor, especially in the chiasmatic region, and that the ophthalmologist is often the first physician to be consulted. Such cases may assume medicolegal importance and are espe-

cially important in an ambulant soldier whose chief complaint is severe head pain. The papilloedema, the skull radiograph, and the type of cephalalgia are the chief factors in diagnosis. In the case described the ophthalmodynamometer of Baillart demonstrated increase of intracranial pressure.

Eugene M. Blake.

Rubino, A. Chiasmal syndrome associated with endocraniosis hyperostotica (Morgagni). *Riv. Oto-Neuro-Oft.*, 1942, v. 19, March-April, pp. 101-132.

Two patients are described. The disease, which was first mentioned by Morgagni (1765) is best named hyperostosis frontalis interna. Rubino considers an opticochiasmatic arachnoiditis to be the main pathogenetic factor and neurohypophyseal complications should be explained as sequelae. Circulatory disturbances are a predominant feature of the syndrome, and were obvious, in Rubino's patients, ophthalmoscopically as well as roentgenologically. (13 illustrations, bibliography.)

EYEBALL AND ORBIT

Azzolini, Umberto. Anterior noncommunicating encephalocystocele. *Riv. Oto-Neuro-Oft.*, 1942, v. 19, Sept.-Oct., pp. 338-350.

An 11-months-old male infant had an anterior encephalocystocele as large as his fist which increased during crying. It was reducible by pressure during the first weeks of life, but not later. It was situated between the right ethmoid and frontal bones and contained cerebrospinal fluid. The author assumes that the encephalocystocele lost its communication with the subarachnoidal space because of an inflammatory proc-

ess, probably congenital syphilis. Only four similar cases have been described previously (Bibliography, 3 illustrations.) K. W. Ascher.

Cadili, G. Osteoma of the maxilla with encroachment on the orbit. *Riv. di Oftalm.*, 1946, v. 1, July-Aug., pp. 459-472.

Partial removal of a maxillary osteoma reduced the disfiguring exophthalmos without interfering with the function of the eye. (4 figures, bibliography.) K. W. Ascher.

Courville, C. B., and Schillinger, R. J. Intracranial complications of the eye and orbit. *Bull. Los Angeles Neurol. Soc.*, 1946, v. 11, Sept.-Dec., pp. 102-110.

In a series of thirty thousand autopsies the authors found only one proven case of orbital actinomycosis that had caused secondary intracranial complications. Malignancies can extend along the optic nerve or erode intracranially. Trauma may simultaneously involve the orbit and cranial cavity. Infections and granulomas of any origin may invade the intracranial cavity and cause septic meningitis or thrombosis of the cavernous sinus. However, the rare orbital tuberculomas or syphilomas almost never extend intracranially.

O. H. Ellis.

Godtfredsen, Erik. Ophthalmoneurological symptoms in connection with malignant nasopharyngeal tumours. *Brit. Jour. Opth.*, 1947, v. 31, Feb., pp. 78-100.

Malignant nasopharyngeal tumors are of fairly rare occurrence, but are more frequent in males. Ophthalmologic symptoms are often present. These symptoms occur chiefly in the period when the exact diagnosis has

not yet been made, but the ophthalmologist should be able to diagnose them correctly. The eye symptoms in decreasing order of frequency were sixth nerve paresis, paresis of the third nerve, visual pathway lesions, paresis of the fourth nerve, Horner's syndrome and exophthalmos. The ophthalmoplegias generally manifested themselves as massive paralyses with associated clinical findings. The visual pathway lesions presented various degrees of severity from a slight impairment of vision to the more frequent total amaurosis with atrophy of the optic nerve or choked disc. Local rhinologic and otologic symptoms occur and large metastatic cervical glands appear early.

Intensified irradiation produced a remarkable percentage of five year cures. (16 illustrations.) O. H. Ellis.

Juzefova, F. I. Experimental investigations on the pathogenesis of metastatic ocular tuberculosis. *Vestnik Oft.*, 1946, v. 25, pt. 6, pp. 7-13.

This is a report of a detailed study on guinea pigs. There were three series of experiments. In one a culture of tubercle bacilli was introduced into the vascular system of the guinea pig; in some of them one eye was subjected to trauma. In another series the guinea pigs were sensitized to horse serum by repeated injections. The final dose was introduced into various tissues of the eye. A culture of tubercle bacilli was introduced into the blood at the same time. A third series, for control, was only sensitized to horse serum. In the first series a high immunologic state of the ocular tissues resulted. Only one of the nine animals developed a tuberculous choroiditis; apparently the trauma was ineffective. In the sec-

ond series 18 out of 20 animals developed a nodular tuberculosis at the site of the last traumatizing injection and in the iris. In the nontraumatized eyes the tuberculous process involved the choroid. These findings demonstrate conclusively the role of the preliminary sensitization in the development of ocular tuberculosis. The hypersensitivity which favors the development of tuberculosis need not be a tuberculous allergy. The ocular lesions of the animals of the third series had no specific character.

Ray K. Daily.

Kisner, W. H., and Mahorner, H. **Unilateral exophthalmos: an early sign in thyrotoxicosis.** *Surg. Gyn. and Obstet.*, 1947, v. 84, March, pp. 326-331.

As an early sign of hyperthyroidism, unilateral exophthalmos is not rare. It may be the only sign of incipient toxic goitre and may precede by months all other subjective and objective findings. Vascular lesions and tumors are the most frequent causes for unilateral exophthalmos.

According to Cavity this condition is sometimes confused with upper lid retraction (Dalrymple's sign). Again there may be bilateral proptosis but the fact that both eyes share in this sign is not recognized. Cavity reported three cases where this sign was the first sign in Graves' disease and the diagnosis was not established until 6, 8, and 20 months had elapsed.

The authors discuss the cause, pathology, treatment, and some experimental work on exophthalmos. They feel that there is little doubt that in some cases of Graves' disease the immediate effect of thyroidectomy is unfavorable. Many weeks or months later the process subsides and usually the eyes return to normal. Radical pro-

cedures such as the Naffziger operation should be deferred for as long as two years after thyroid removal.

Francis M. Crage.

Kogan, N. D. **Fire-arm injuries of the orbit.** *Vestnik Oft.*, 1945, v. 24, pt. 4, pp. 11-15.

On the basis of a clinical experience with 48 orbital wounds Kogan concludes that the gravest injuries are the orbitocranial or those involving the sinuses. Orbital injuries should have a roentgenologic as well as a neurologic examination. In isolated perforating ocular injuries one should keep in mind the possibility of a double perforation with penetration of fragments into the skull, and subsequent neurologic complications. Surgical intervention should be a joint task of the ophthalmologist, rhinologist, and neurosurgeon. Provision of ophthalmologic service at the front or prompt transport of the wounded to specialized hospitals is the best prophylactic measure against complications and death.

Ray K. Daily.

Longhena, Luisa. **Cranio-orbital fracture complicated by diplococcic meningitis.** *Riv. Oto-Neuro-Oft.*, 1943, v. 20, March-April, pp. 94-111.

An apparently slight injury to the orbit suffered during an air raid was followed by a fatal meningitis. Purulent posttraumatic meningitis usually results from an infection that penetrates through a cranial fracture into the subarachnoidal space. Often, the first meningeal signs appear before the surgeon realizes that there is a bony lesion. Even without infection in the accessory nasal sinuses, a severe meningitic complication may follow the injury, due to the presence in the normal

mucous membranes of a varied bacterial flora. Negative nasal examination and initially good condition of the patient do not warrant a favorable prognosis. Injury to the dura and to the brain proper increases the danger. (2 figures, bibliography.)

K. W. Ascher.

Marin Amat, M., and Diaz Gomez, E. **Exophthalmos in orbitocranial tumor.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Feb., pp. 190-202.

A 24-year-old woman with a marked exophthalmos of the left eye had pallor of the optic disc, large and tortuous veins, and slight concentric contraction of the peripheral field in the left eye and slight pallor of the papilla with enlarged veins and temporal hemianopsia in the right. A diagnosis of orbitocranial tumor was made. The operation showed that the exophthalmos was due to a tumor mass of the cranial cavity that had spread to the orbit. (6 illustrations.) J. Wesley McKinney.

Marucci, L. **Bilateral exophthalmos of unequal degree.** *Rassegna Ital. d'Oftal.* 1941, v. 10, Sept.-Oct., pp. 527-538.

Slight bilateral exophthalmos occurred in a man, 38 years of age. Periodically there was an increase in the proptosis and some edema of the lids, hyperemia of the conjunctiva, but no feeling of distress. The author concludes that there is an intraorbital angioma, with a neurovascular lability, that results in an augmentation of the exophthalmos of the right eye. Roentgen radiation brought about a satisfactory result, both as to the exophthalmos and the crises. E. M. Blake.

Mastrangeli, Wilfredo. **Tuberculoma of the orbit.** *Riv. di Oftalm.*, 1946, v. 1, July-Aug., pp. 446-458.

Di Marzio distinguishes the following types of orbital tuberculosis: secondary to tuberculous disease of the eyeball; extension from the orbital bones or accessory sinuses of the nose; isolated orbital tuberculosis; symmetrical tuberculosis of both orbits. In a woman, 58 years of age, a tentative diagnosis of orbital tumor led to removal of a tumor measuring 3 by 1 centimeters. Histologically, a miliary hyperplastic tuberculosis was diagnosed (two microphotographs). The Pirquet reaction was strongly positive, and an X-ray examination showed residual unilateral pleuritis. Not infrequently an orbital tuberculoma may be mistaken for a neoplasm. K. W. Ascher.

Olivella, Antonio. **Intermittent exophthalmos.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Sept., pp. 905-912.

A case of a young man is reported, who within a year developed an intermittent exophthalmos of the left eye. A detailed clinical study showed that the exophthalmos was due to an orbital varicocele. J. Wesley McKinney.

Renard, G., and Offret, G. **Angiomas of the orbit.** *Arch. d'Ophth.*, 1946, v. 6, no. 3, pp. 284-313.

Orbital angiomas are more common than is generally realized and removal is necessary in the majority of instances. Surgical removal in toto is the only logical procedure.

Cavernous angioma is the most common anatomic form. It is a well-defined tumor of variable size and location with a tendency to localize near the inner wall of the orbit. The tumor commonly displaces the globe forward and laterally and may deform it by pressure inducing ametropia. Radiographic study shows enlargement of the orbit on the affected side. The authors call

attention to the fact that symptoms of angioma commonly appear in childhood but do not become incapacitating until adult life. Although these tumors are usually removable without difficulty, in exceptional instances adhesions to the extraocular muscles have occurred. Complications of operation include ptosis, oculomotor paralyses, anesthesia of the cornea, and optic atrophy. The authors describe in detail the microscopic anatomy of cavernous hemangioma, defining three anatomic types, cystic angioma, angioliipoma, and hemolymphangioma.

Simple angioma, while less common, is more variable and is capable of greater extension. It frequently extends beyond the orbit and is associated with nevus flammeus of the lids and of the face. Simple angioma has no capsule and tends to infiltrate widely in the orbit, menacing the integrity of all the intraorbital structures. Its surgical removal is difficult and is often followed by hemorrhage and sensory and motor disturbances. The histopathologic characteristics of this tumor are also described in detail.

In a discussion of the pathogenesis of orbital angioma the authors note its congenital nature and the lack of any hereditary or definitely predisposing factors. Phillips Thygeson.

Schneider, J., and Frankel, S. S. Treatment of late postoperative intraocular infections with intraocular injection of penicillin. *Arch. of Ophth.*, 1946, v. 37, March, pp. 304-307.

In two patients extracapsular cataract extraction was followed by late intraocular infection and was treated with intraocular injections of penicillin. In each case final vision was light perception.

The authors conclude that the intra-

ocular injection of penicillin for late postoperative infections is well tolerated by man and the eye may be saved from evisceration by early injection of penicillin. R. W. Danielson.

Shmeleva, Z. G. Some characteristics of ocular tuberculosis in the postwar period. *Vestnik Oft.*, 1946, v. 25, pt. 6, pp. 25-28.

Thirty-two patients with metastatic ocular tuberculosis were treated with tuberculin, and 12 with nonspecific therapy. An analysis of the material in comparison with prewar patients shows a shift towards an older group of patients, a greater general and local sensitivity, and a tendency to punctate hemorrhages, sometimes as focal reactions. These new tendencies in the clinical course call for greater caution in tuberculin therapy, and for the combination of this form of therapy with general hygienic and supportive measures. Ray K. Daily.

Stallard, H. B. A plea for lateral orbitotomy (Krönlein's operation). *Brit. M. J.*, 1947, March 29, pp. 408-409.

The Krönlein operation is preferred to the transfrontal technique in the removal of a neoplasm the physical signs of which show it to be entirely within the orbital cavity. There is more direct and adequate exposure. A case of a neurofibroma situated within the muscle cone, which was missed by the transfrontal approach is presented.

Irwin E. Gaynon.

Talkovsky, S. I. Ophthalmic symptoms of aneurism of the internal carotid in anophthalmos. *Vestnik Oft.*, 1945, v. 24, pt. 4, pp. 23-26.

Talkovsky saw four fire-arm injuries, with the point of entry at the temple, and exit from the orbit, followed by

destruction of the eyeball, and the development of an arteriovenous aneurysm of the internal carotid. The anophthalmos and the consequent absence of a pulsating exophthalmos obscured the presence of the aneurysm; the only symptom that arrests attention is the persistent edema and swelling of the soft tissues that results from the venous congestion of the orbit. The diagnosis is important because an attempt to enucleate the remains of the eyeball may lead to fatal hemorrhage. These patients need special vocational guidance, because even insignificant trauma may result in serious complications.

Ray K. Daily.

Weizenblatt, S. **Penicillin in treatment of acute endophthalmitis.** *Arch. of Ophth.*, 1946, v. 36, Dec., pp. 736-738.

A man, 49 years of age, had Elliott's trephine operations in each eye five years ago for chronic glaucoma. Six months later the right eye was lost because of infection with *Staphylococcus aureus*. The left eye had had three previous infections from which it recovered. A fourth infection, caused by *Staphylococcus albus* developed in April 1945. There was a purulent infiltration of the bleb, hypopyon and yellow reflex behind the lens. Treatment consisted of atropine, instillation of penicillin drops (2,500 units per c.c.) every hour, the oral administration of sulfadiazine, penicillin intramuscularly in 20,000-unit doses every four hours, and typhoid vaccine intravenously. Under this regimen the eye became worse. Two-tenths cubic centimeter of penicillin solution (2,500 units per c.c.) was injected into the vitreous. About 24 hours later glaucoma developed and atropine was discontinued. Practically complete recovery resulted, with normal pressure and vision of 20/20. Re-

peated infections of the bleb did not result in formation of scar tissue but lead to thinning of its conjunctival covering, which ruptured spontaneously.

EYELIDS AND LACRIMAL APPARATUS

Arisi, Ebe. **Morphologic study of the bony lacrimal fossa and lacrimal duct.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, July-Aug., pp. 298-304.

The axes of the fossa of the lacrimal sac and the lacrymonasal duct vary considerably in direction. The more acute this angle the greater is the predisposition to the retention of tears. Dacryocystitis develops in the great majority of cases from stenosis at the level of the junction of the sac and the duct. The white race is more subject to stenosis than the negro. Arisi concludes that the angle formed by the two axes is almost always more acute on the right side, is more obtuse in brachycephalic heads, and more acute in dolicocephalic heads. (5 figures.)

Eugene M. Blake.

Brognoli, Carlo. **Considerations in the surgical treatment of ptosis.** *Arch. di Ottal.*, 1946, v. 50, July-Aug., pp. 169-192.

The surgical treatment of ptosis was divided by Terrien into four groups: 1. a shortening of the lid by excision of a strip of skin from the lid, 2. the use of the frontalis muscle as an elevator of the lid, 3. advancement, or advancement plus shortening of the levator palpebrae, 4. the use of the superior rectus as an elevator. Brognoli describes representative procedures in each group and evaluates each. Variations of the methods in the third and fourth group were used almost exclusively in

the series reported. Brognoli feels that utilizing a part of the superior rectus as the elevator of the lid has one defect in that the binocular vertical balance is disturbed. This is true when a transplantation is done by the methods of Motais and Bardelli, or a symblepharon is created between the lid and the eyeball by the method of Nida. Shortening and advancement of the levator muscle, whether paretic or paralyzed, seemed to yield the most satisfactory results, using the method of Blaskovic. The method is described in detail. The use of different colored sutures for different tissues is advocated to eliminate confusion. (18 photographs.) Francis P. Guida.

Czokrász, Ida. **Contributions to total blepharoplasty.** Brit. Jour. Ophth., 1947, v. 31, Feb., pp. 108-113.

Three cases are presented, which illustrate different methods of substituting the total lack of eyelids. Hughes's method is equally adaptable to restore the upper or lower lid. Blaskovic's second operation is suitable when the whole upper lid is missing. The Hungarian plastic generally is used only for substituting the lower lid, but when both lids are lacking the sliding flap is recommended. With loss of both upper and lower lids replacement at once with one arched plasty is indicated, if one is to hope to save the globe. (11 figures.) O. H. Ellis.

Filatov, V. P. **Plastic reconstruction of the lids with a round pedicle.** Vestnik Oft., 1945, v. 24, pt. 3, pp. 9-10.

Filatov advocates using flaps with round pedicles from the forehead, or the lid of the other eye for plastic reconstruction of the lids. To illustrate their use, he reports three cases, in one of which the left eyeball was left with-

out the protection of the upper lid. The right eyeball was atrophic and the orbit deformed. By means of a round pedicle Filatov used the tissue of the right upper lid for the reconstruction of the left upper lid. Ray K. Daily.

Friberg, Torsten. **Physiologic considerations in the treatment of the lacrimal passages.** Acta Ophth., 1941, v. 19, pt. 2, pp. 93-108.

The conventional methods of examination and differential diagnosis for the site of the obstruction in the lacrimal passages are reviewed. The author defends Bowman's operation for stenosis of the lacrimal punctum. He regrets that the West-Polyak intranasal operation has not obtained its deserved popularity probably because ophthalmologists find it difficult to acquire a good intranasal surgical technic. Patients with epiphora consult the ophthalmologist first, and are subjected to some other surgical procedure. (Illustration.) Ray K. Daily.

Gandolfi, C. **Primary epithelioma of the lacrymal sac.** Rassegna Ital. d'Ottal., 1941, v. 10, Nov.-Dec., pp. 576-585.

The bibliography of tumors of the lacrimal sac is reviewed and an instance of primary epithelioma is reported. The tumor was of the papillary type. There follows a discussion of the clinical differential diagnosis of neoplasms of the lacrymal sac. (2 figures.) Eugene M. Blake.

Garbino, Carlos. **Allergic reactions to tears from tuberculous patients.** Arch. de Oft. de Buenos Aires, 1943, v. 18, Nov., p. 617.

By means of intradermal tests the author studied the reaction to tears. In the first group he injected tears from allergic children into allergic and non-

allergic ones. A positive reaction was obtained in all allergic children. In the second group the injection of tears from nonallergic children into allergic ones caused no reaction. Children with phlyctenular keratoconjunctivitis as well as healthy ones were used in these experiments. The author concludes that these tests are specific reactions similar to those of tuberculin. (Tables, bibliography.) Plinio Montalván.

Haas, M. E. Ablation of the orbital lacrimal gland. *Ann. d'Ocul.*, 1946, v. 179, Sept., pp. 497-502.

Following an anatomical review, the surgical indications are mentioned. These include prolonged and resistant epiphora due to numerous causes. Chloride of calcium is given several days before the operation to prevent bleeding and hemocoagulin is injected one-half hour before operation. Regional anesthesia with 2 c.c. of 4-percent procaine solution is used. A skin incision is made at the upper temporal orbital margin. The incision is then deepened to include the periosteum which is raised with an elevator. The gland which is fixed by a suture, is dissected with scissors. Deep and superficial sutures of 3-0 catgut are used to close the wound. Chas. A. Bahn.

Ivanova, E. M. Rhinostomy; and its indications. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 12-14.

Averbach was a strong champion of dacryocystorhinostomy, and under his direction 6000 operations had been performed at the Institute. On the basis of this clinical experience Ivanova concludes that the operation is indicated in all cases of purulent dacryocystitis, and that it has no contraindications.

Ray K. Daily.

Kanbai, G. G. Restoration of the lacrimal canaliculus in plastic surgery of the lower lid. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 83-85.

Three cases are reported in which fire-arm injuries of the face involved the lower lid and the lacrimal canaliculus. Plastic restoration of the lower lid was combined with suture of the torn ends of the canaliculus over a probe, which remained in place several days. The results were satisfactory.

Ray K. Daily.

Khaiutin, S. M. Surgical restoration of the lids. *Vestnik Oft.*, 1945, v. 24, pt. 4, pp. 26-28.

Khaiutin utilized the cicatricial tissue of the lid for the inner layer of the new lid, by separating it from the tissues and turning it towards the palpebral fissure. The outer layer of the lid is formed by a pedicle graft from the temple. The author found this technic satisfactory, the results permanent, and the post-operative period comparatively short. (3 illustrations.)

Ray K. Daily.

Lagos, E. J. J. Dacryocystorhinostomy. Technique of Dupuy-Dutemps-Bourguet-Valle. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 639.

The author discusses the advantages of dacryocystorhinostomy over dacryocystectomy in the treatment of dacryocystitis. He prefers the Dupuy-Dutemps-Bourguet-Valle technique and describes the preoperative management of the patient, with special attention to the condition of the lacrimal passages and the nose. The indications and contraindications for dacryocystorhinostomy are discussed. His experience in over 100 operations is briefly reviewed.

Plinio Montalván.

Lloyd, I. A survey of the results of lacrimal stricturotomy. *Brit. Jour. Ophth.*, 1947, v. 31, Jan., pp. 51-54.

The author performed 33 stricturotomies on 31 patients according to the method used in the French clinics. The lower canaliculus is opened with a Weber knife for 3 mm. and dilated with a number 3 sound. The stricturotomy knife is passed down into the sac and engaged in the neck of the duct. It is then verticalized and rotated through an angle of 45 degrees. Gum-elastic sounds from number 11 to 14 are passed and the largest left in situ for 10 minutes. Dilatation is continued at intervals of two weeks for two months.

The French claim 100 percent of patients are cured when there is no bony obstruction and 70 percent when there is. In the hands of the author 52 percent were cured and 24 percent much improved. He feels that the technique possesses many advantages over ordinary probing and that its benefits are considerably more substantial.

Morris Kaplan.

Malbrán, J., and Arrechea, A. Filamentous keratitis and keratoconjunctivitis sicca. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 603.

The authors report four cases of keratoconjunctivitis sicca. They tabulate the symptomatology, review the literature in detail and conclude that filamentous keratitis is due to lacrimal hyposecretion or keratoconjunctivitis sicca, which may result from different causes. The diagnostic value of the Schirmer test is emphasized. (Bibliography.)

Plinio Montalván.

Morano, Massimo. Connections between dacryocystitis and paranasal sinus affections. *Riv. Oto-Neuro-Oft.*, 1943, v. 20, Jan.-Feb., pp. 40-63.

Between January, 1939, and May, 1942, the Bologna ophthalmologic department treated 380 patients with inflammation of the lacrimal sac. Fifty-four had peridacryocystitis complicated by inflammation of the anterior ethmoidal cells, seven complicated by polysinusitis, and only five were without sinus disease. Among those who had only an infection of the lacrimal sac itself, were 66 with anterior ethmoid involvement, one with polysinusitis, and 247 without any paranasal sinus disease. The latter occurs in 92, of 4 percent of all peridacryocystitic processes, and in only 21, or 3 percent of dacryocystitis without involvement of the surrounding tissues. The importance of exact nasal and X-ray examination is stressed. (13 excellent X-ray pictures, 24 references.)

Suarez Villafranca, M. R. Malformation of the lacrimal passages; an embryologic study. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Oct., pp. 1027-1037.

The embryology of the lacrimal passages is reviewed, and a case of congenital malformation reported. The 18-months-old child had a congenital coloboma of the left lower lid. There was a mass the size of a pea on the tarsal conjunctiva at birth which gradually increased to the size of a walnut. At the age of three months an attempt at surgical repair of the coloboma failed. There was a fistulous tract in the nasolabial angle, from which a mucopurulent secretion exuded. Pressure on the mass expelled a clear and then a mucopurulent fluid through the misplaced inferior canaliculus. Three surgical procedures were performed: excision of the mass, excision of the fistulous tract, and a plastic operation for repair of the coloboma. Histologically the fistula was found to be lined with cylindric epithelium over a layer of flat cells and the stroma was infiltrated with lymphocytes. The anomaly was probably produced by a failure of the nasal and maxillary bones to coalesce; the disturbance in this region lead to coloboma of the lid, facial asymmetry and incomplete development of the left side of the nose. In the sixth week of embryonic life an epithelial bud forms from which the lacrimal passages develop. If in its development the ectoderm fails to disappear, its invagination into the mesenchyme is disturbed, and it is not included in the osseous lacrimonasal canal. A second possibility is an interference with the closure of the orbitonasal sulcus and a failure to include the lacrimonasal passages.

Ray K. Daily.

Tikhomirov, P. E. The relation between epiphora and nasal pathology. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 28-34.

The literature is reviewed and the relevant clinical data in 100 persons with epiphora, and 50 persons from the rhinologic clinic with various nasal diseases are reported in detail. The correlation of the data leads to the conclusion that stenosis of the lacrimonasal canal which leads to dacryocystitis is usually associated with a diseased mucous membrane of the nose. Epiphora due to changes in the upper portion of the lacrimal apparatus has no relation to nasal abnormalities. In reflex epiphora due to hypersecretion of the lacrimal gland nasal lesions are not infrequent, but their etiologic role is difficult to evaluate, because treatment of the nose does not always lead to cessation of the epiphora.

INJURIES

Brodsky, B. S. The scleral incision in extraction of foreign bodies from the eye. *Vestnik Oft.*, 1946, v. 25, pt. 3, pp. 12-14.

Brodsky opens the eyeball by means of a trephine opening through the sclera. In 10 of 12 patients no incision in the choroid and retina was necessary.

Ray K. Daily.

Carrearas Duran, B. An unknown intraocular foreign-body. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Sept., pp. 926-933.

A man, 24 years of age, had an intraocular foreign body for many years of which he was not aware. For the last two years he had gradually lost vision in his right eye, but before this time his eyes had never given him any trouble. Upon examination an enlargement of the volume of the right eye, a fine corneal scar and optic disk atrophy with deep glaucomatous cupping were found. Tension was 50 mm. of Hg. The left eye was normal. A diagnosis of absolute secondary glaucoma due to intraocular foreign body was made. The eye was enucleated and a small piece of steel was found embedded in the internal retinal layer.

J. Wesley McKinney.

Chechik-Kunina, E. A. Lysozyme in the treatment of burns and perforating ocular injuries. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 42-44.

From the study of 54 patients, the author concludes that in perforating ocular injuries the lysozyme titre is diminished, and that the number of infections is in direct relation to the diminution of lysozyme in the tears.

The titre of lysozyme can therefore be used as a prognostic indication. Clinical instillation of lysozyme into the conjunctival sac every two hours acts favorably in perforating ocular injuries, and in burns in which conservative therapy is effective. Laboratory experiments on rabbits confirmed the effectiveness of lysozyme in burns.

Ray K. Daily.

Ershkovish, I. G. Tissue therapy with Filatov's method in traumatic iridocyclitis. *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 13-20.

Fifty-eight patients with severe traumatic iridocyclitis after perforating injuries were studied; 36 patients had only one eye, and 28 eyes contained foreign bodies. In 35 there were additional injuries in other parts of the face. In 29 patients tissue therapy was the only therapeutic procedure; in the others tissue therapy was given preliminary to surgical procedures, which could not be performed because of severe inflammatory symptoms or were not indicated because of imperfect light projection. Tissue therapy arrested the inflammatory process, and frequently made surgery possible on an apparently hopeless eye. The tabulated data show that only three of the 58 patients remained without improvement. (1 table.)

Ray K. Daily.

Ershkovich, I. G. The treatment of so-called hopeless ocular war injuries. *Vestnik Oft.*, 1945, v. 24, pt. 4, pp. 19-22.

Because of the results achieved with tissue implantation therapy Ershkovich believes that our prognostic standards need revision. Cases are reported to illustrate that eyes with lesions in the anterior segment and faulty light projection can be given some vision by

means of tissue therapy and surgery. The hopeless prognosis of severe injuries of the optic nerve and retina should also be modified; eyes with dense vitreous opacities, with traumatic chorioretinitic foci involving the macula have been benefited by therapy. Illustrative cases are reported.

Ray K. Daily.

Filatov, V. P. **Optic operations on subatrophic eyes.** *Vestnik Oft.*, 1945, v. 24, pt. 3, pp. 8-9.

Filatov urges that an effort be made to restore to every soldier some degree of vision. For this purpose he advocates prolonged tissue therapy preliminary to surgery. After tissue therapy faulty light projection may become normal. After that, dissection of organized exudates may lead to restoration of some degree of vision. Two case histories are reported as illustrations. One patient recovered vision of 3/100, and the other 2/100. Even such low visual acuity is appreciated by patients, and no effort should be spared to attain it. Even eyes in the process of atrophy, with faulty light projection should be treated in the hope of recovering light projection, and be given the benefit of optic operations. In seven out of 25 eyes some vision was thus restored.

Ray K. Daily.

Kantorovich, A. I. **The indication for extraction of intraocular foreign bodies in old war injuries.** *Vestnik Oft.*, 1945, v. 25, pt. 3, pp. 14-17.

A clinical experience with 35 cases shows that late removal of intraocular foreign bodies is much more complicated than early operation. It is even more difficult to establish the magnetic character of foreign bodies after a time. The author believes that a foreign body of long standing in an only eye which

has some vision and is free from inflammatory symptoms is best left alone. An attempt at extraction should be made only when there is an intractable iridocyclitis. If the magnetic test is positive in a patient who has one sound eye the foreign body should be extracted, even if the eye is quiet. With a negative magnetic test accurate localization with X ray is indispensable. A foreign body imbedded in the ocular wall should be extracted through a window opening in the sclera.

Ray K. Daily.

Kolarsz, E. K. **Electromagnetic surgery in base hospitals.** *Vestnik Oft.*, 1946, v. 25, pt. 3, pp. 9-12.

The large number of ocular injuries in the last war is due to the predominance of artillery fire. Ninety percent of the ocular injuries were caused by fragments, 9.8 percent by bullets, and 69.6 percent of the ocular injuries had intraocular foreign bodies. Only 1.2 percent of these patients reached the base hospitals within ten days after the injury; most of them arrived there one month after the injury and later. Of 245 foreign bodies, 139 were successfully extracted. In 11.8 percent of the patients the eyeball was subsequently enucleated because of a severe post-operative iridocyclitis. In 2.4 percent retinal detachment appeared three to four weeks after the extraction. The author urges extraction within two to three days after the injury, electrocoagulation of the edges of the scleral incision, and the application of the electromagnetic test when foreign bodies are suspected. (3 tables.)

Ray K. Daily.

Levkoeva, E. F. **Ocular injuries.** *Vestnik Oft.*, 1945, v. 24, pt. 3, pp. 11-19.

On the basis of the histologic examination of 6,000 eyeballs enucleated after

various trauma, Levkoevā sought to evaluate their clinical management. One is impressed with the fact that ocular wounds can not be managed on general surgical principles. The eyeball represents a closed complicated system, with unstable interrelationships of its inner portion; insignificant disturbances, small exudates or hemorrhages may lead to loss of the eye. This is particularly the case in peripheral injuries to the cornea and sclera which maintain the shape of the eyeball. In more or less extensive injuries of this capsule with gaping of the wound, the mechanical abnormality may lead to a disturbance of the intraocular metabolism with all its dire consequences. The first and immediate concern of the surgeon should be accurate closing of such wounds and restoration of normal anatomic relationships, leaving the danger of infection or sympathetic ophthalmia for later consideration. The histologic sections indicate definitely that not closing the wound with sutures is equal to trusting to luck. A Kuhnt conjunctival flap is inadequate to close the wound, and its main objective is the prevention of infection, and not adequate wound closure. Levkoeva vigorously condemns the use of the Kundt flap because it gives false security and she urges the development of a standardized technic for firm and accurate closure of corneal and scleral wounds. (5 photomicrographs.)

Ray K. Daily.

Loginov, G. G. Comparative evaluation of Kundt's conjunctival flap and sutures in the management of ocular wounds. *Vestnik Oft.*, 1945, v. 24, pt. 3, 21-27.

Thirty-seven injured eyes were studied; 19 had corneal wounds, nine scleral, and nine had post-operative

wounds of the anterior portion. When streptocide powder is used the results are better with sutures, than with the conjunctival flap. The defects of the Kuhnt flap are the imperfect coaptation of the edges of the wound, and the prolific growth of connective tissue within the wound. The merit of the Kuhnt flap is the ability to prevent prolapse of uveal tissue and to prevent infection, but these objectives are achieved just as well with sutures. The sutured wound has well coapted edges, withstands raised intraocular tension, and prevents secondary invasion of the wound by microorganisms. There is less connective tissue formed within the sutured wound and within the eyeball. Sutures of the sclera also limit penetration of connective tissue growth. Suturing of the wound shortens the post-operative period. In most severe injuries the sutured eyeball retains its shape. The variety of wounds and their location does not permit the use of visual acuity as a criterion for the effectiveness of the wound closure.

Ravasini, C. A case of rupture of the sclera with luxation of the lens beneath Tenon's capsule. *Rassegna Ital. d'Ottal.*, 1941, v. 10, Sept.-Oct., pp. 451-486.

The author describes a case of equatorial rupture of the sclera with luxation of the lens in the posterior segment of the globe, beneath Tenon's capsule. He gives a detailed macroscopic and microscopic description and discusses the pathogenesis and the characteristics of scleral rupture. The scarce literature on this subject is reviewed and abstracted, and demonstrates that for the lens to be dislocated posteriorly the tear in the sclera must be equatorial.

Rodigina, A. M. Surgery of perforating ocular injuries. *Vestnik Oft.*, 1945, v. 24, pts. 1-2, pp. 53-55.

On the basis of clinical experience and experimental work on rabbits, Rodigina advocates suture of corneal and scleral wounds. When there is no injury to the lens, such wounds heal without infection even if sutured several days after the injury. Eyes with injury to the lens healed better when sutured, but dense cicatricial tissue that develops around the lens often leads subsequently to shrinking of the eyeball.

Sená, José A. Errors in the roentgenologic diagnosis of intraocular foreign bodies. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 622.

After discussing the value of the roentgenologic investigation of intraocular foreign bodies, the author reports three cases to prove that this

procedure is not always absolutely accurate. In one patient a defect in the X-ray apparatus led to a diagnosis of intraocular foreign body, the existence of which could be disproved by the history and clinical examination. In another the foreign body was clinically located and removed in spite of negative plates. In the third the X-ray film definitely led to a diagnosis of foreign body outside the globe, but the clinical examination and surgical removal proved it to be intraocular. The author emphasizes the importance of a careful clinical examination, to which all other diagnostic procedures must be subordinated.

Shershevskaya, O. Treatment of war invalids for sequelae of injuries of the eyeball and its adnexa. *Vestnik Oft.*, 1945, v. 24, pt. 4, pp. 15-19.

This material consists of invalids, from one to three years after the injury. The striking feature was the fact that the pathologic process in the eye was not yet completed; in some apparently hopeless eyes massive exudates in the vitreous became absorbed, whereas some eyes which were quiet for a long time suffered severe damage from exacerbations of an old iridocyclitis. Such exacerbations may occur in eyes several years after a perforation in any portion of the eyeball, even without an intraocular foreign body. These processes testify to the great virility and pathogenicity of latent infectious processes within the eye. The lesions were varied, and usually severe and complicated; most eyes had had some surgical repair in the base hospitals. Persistent efforts were made to restore some degree of vision. As an example the case of a 21-year-old man is reported. His only eye had an almost complete leucoma, with a small area of

clear cornea close to the limbus, through which one could see the atrophic iris adherent to the cornea. The first operation was a keratoplasty with resection of the adherent iris; the cataractous lens, which then became visible was removed at a second operation six weeks later. Corrected vision was 0.06. Later glaucoma developed, which was controlled by paracentesis. The clinical experience with this group of patients demonstrates that old exudates in the vitreous may be absorbed under intensive therapy, and considerable vision obtained. An original procedure described is an excision of the sphincter of the iris with the cicatricial membranes attached to it. After a corneal incision a small knife punctures the sphincter, and with a sawing motion the entire sphincter is cut away from the iris; the sphincter with the lens capsule and organized exudate is removed with forceps. Preliminary X-ray irradiation is probably important in the smooth postoperative recovery.

Pedicle grafts were used for plastic repair of the lids. Ray K. Daily.

Stellard, H. B. The intraocular foreign body. *Brit. Jour. Ophth.*, 1947, v. 31, Jan., pp. 12-40.

This long, detailed article is the report of 72 cases of penetrating wounds of the eye with retained foreign body and is a sequel to a report of 102 such cases previously reported. They occurred in the campaigns in the Western Desert and in Normandy. The majority of foreign bodies produced by fragmentation of modern air missiles are so slightly magnetic that the technique of localization and extraction differs from that in civil practice. The "magnet test," pain caused by waving the magnet over the eye, was negative in many cases, and yet if the giant magnet tip

was placed very close to the foreign body its extraction was effected.

Investigation must be complete. Many wounds of entry are well healed at the time of examination, and all the surrounding adnexa must be carefully studied. In one case a shell splinter entered the occiput, traversed the intracranial contents, entered the orbit from behind, penetrated the sclera and came to rest in the vitreous while the patient remained completely unaware of it.

Aluminium and some nonmetals give rise to no signs of irritation within the eye and if not large enough to obstruct vision are best left alone. Small pieces of glass and bakelite were left alone but copper and stone caused violent inflammation. Localization was accomplished by ophthalmoscopy in 45 patients. X-ray was used on all the others. The Sweet and Dixon methods are the most ideal but were entirely unsuited for mobile warfare. A limbal ring sutured to the conjunctiva was used and served well enough.

For extraction, the posterior scleral route was much preferred with the use of the Solus giant electromagnet. The instrument was always mounted on a stand. The area around the incision was always subjected to diathermy and no retinal separation or even vitreous loss was experienced. Stallard insists that retinal detachment does not follow careful surgery. There were no infections.

Visual results were very satisfactory. Morris Kaplan.

Gilbert, T. M., and Hing, S. R. The Stevens-Johnson syndrome. M. J. Australia, 1946, v. 2, Nov. 30, pp. 774-776.

The occurrence of Stevens-Johnson syndrome in a 40-year-old soldier is described. The patient had typical lesions of the oral mucous membranes, followed by a sloughing pseudomembrane. There was bilateral purulent conjunctivitis, in the course of which conjunctival bullas eventually developed. The patient had a moderate hyperpyrexia, and an exanthematous dermatitis that resembled erythema multiforme.

On the fifth day, pneumonia developed. The patient was treated with penicillin systemically and locally in the eyes. Within two weeks the conjunctivitis and stomatitis had cleared up, and the patient was discharged as completely cured after five weeks. The conjunctival blebs and the pulmonary complications were considered to be unusual features. Benjamin Milder.

Gordon, D. M. Hemifacial spasm. Arch. of Ophth., 1947, v. 37, March, pp. 282-293.

Hemifacial spasm is a condition in which the patient has paroxysms of twitchings in muscles innervated by the seventh nerve. The condition is not under voluntary control and defies mimicry. Hemifacial spasm is not a tic. The spasm occurs during sleep and is not broken by will. It is usually clonic but may become tonic.

The condition of hemifacial spasm is described and attention called to the fact that at least two forms exist, one idiopathic and the other following regeneration of a traumatized seventh

nerve. An illustrative case of each is presented. Treatment, differential diagnosis, and literature, are discussed.

R. W. Danielson.

Jebejin, R., and Kalfayan, B. Oculobuccogenital syndrome. Ann. d'Ocul., 1946, v. 179, Sept., pp. 481-491.

In a preceding article the authors described this syndrome which consists of acute iritis with hypopyon, ulcers of the mouth and genitals, and nodular erythema. Frequent also is recurrent swelling of the salivary glands with fever and recurrent retinal hemorrhage with proliferative changes, especially in the young. An acid resisting bacillus was found in the sections but its cultural characteristics have not been determined. The authors believe that the initial stage is characterized by phlebitis with recurrences, which may be complicated by more or less obliterative thrombosis, but which usually heal. The symptoms are probably a part of a general infection transmitted through the blood in which phlebitis is an important factor, but in which allergy also plays a part. Behcet, whose name is associated with part of this syndrome suggested that a virus infection is the probable cause. The authors concluded that this syndrome is not an atypical form of tuberculosis. Krutova, A. H. **Primary and secondary eye lesions in tularemia.** *Vestnik Oft.*, 1946, v. 25, pt. 4, 23-26.

A drop of a culture of the organism instilled into the conjunctival sac of one eye of a rabbit produced characteristic granulomatous lesions in every case. The control eye remained normal, except in one animal which had extensive hemorrhages into the lacrimal gland. Nearly all animals died from a generalized infection before the pathologic process in the eye was concluded. The microscopic studies revealed granulomatous foci in the cornea and ciliary muscles. Secondary ocular lesions appear on the eighth or ninth day of the infection, are bilateral, and are not associated with a local lymphadenitis; the clinical symptoms indicate that they are the result of a hematogenous metastatic process, the original focus of which may be in an internal organ. This study emphasizes the importance of a thorough general examination of patients who have apparently recovered from Parinaud's disease.

treatment with gonadotropine. *Rev. Oto-Neuro-Oft.*, 1946, v. 21, July-Aug., pp. 73-81.

This paper presents eight further cases of sellar lesions, which, like three similar ones that have been reported were successfully treated with hormones. In this new series the patients were 16 to 47 years of age, five of them were female. They complained of diminishing visual acuity. The ophthalmoscopic findings included choroidal vascular sclerosis, retinal vascular sclerosis, foveal pigment changes, retinal hemorrhage, macular changes, chorioretinal atrophy, and pale discs. All showed radiographic evidence of sellar changes, such as osteolysis, and rarefaction or decalcification of the clinoid processes. Three of the patients had syphilis, and six showed evidence of endocrinal disturbance. All had mild to severe concentric contraction of the field. After treatment with lobulantine, the majority showed definite improvement in visual acuity. (Bibliography, 8 schematic radiographs.)

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Forbes, G. Microphthalmos. *Brit. Jour. Ophth.*, 1946, v. 30, Dec., pp. 709-715.

The eyes of a six-months-old fetus were microphthalmic and one was removed for serial section. It was 8 mm. in diameter. The sclera presented a fibrous band which divided the ball into a small, anterior, inferior cyst and the larger true eye. This cyst communicated with the vitreous chamber and was lined with choroid and retinal pigment layer. The cyst cavity was filled with disorganized retina that was lying free. The conjunctiva was normal and the cornea was very cellular with no discernible Bowman's membrane. The choroid presented scant pigment, was folded in many places but seemed to line the entire sclera. Ciliary processes were undeveloped and iris muscles could not be seen. The ciliary muscle

was present. The lens was large and spherical and showed several irregular projections; its center was a degenerated cataract. The retina was detached and thrown forward, and had no demonstrable rods and cones.

Normally the fetal fissure begins to close in the 11 mm. stage. In this case some interference occurred earlier, probably between the fourth and sixth weeks since much tissue differentiation was obvious. There was no family history of irregularities and there was no illness of any kind during pregnancy. It was decided, nevertheless, that this malformation originated from a genetic defect or because the mother suffered an unnoticed subclinical infection.

Morris Kaplan.

Gallego, Antonio. Notes on the vasomotor fibers of the retina. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Dec., pp. 1245-1246.

Gallego illustrates with photomicrographs the vasomotor retinal fibers of a dog. The central retinal artery is surrounded by an extensive nerve fiber network which can be followed for large extents. In one case the terminal bulb is seen. Some capillaries are surrounded by a fine network of nerves, without terminal bulbs. (3 photomicrographs.)

Gurchot, C., Krebs, E. T., Jr., and Krebs, E. T. Growth of human trophoblast in the eye of the rabbit; its relationship to the origin of cancer. *Surg. Gyn. and Obstet.*, 1947, v. 84, March, pp. 301-312.

Explants of tissue obtained from normal human placentas aged 2, 5, 7, and 9 months, were placed in the eyes of eight rabbits through incision made at the corneoscleral margin. A description of the sequence of events in each rabbit and the laboratory work which followed is given. The discussion includes 96 references. The results indicated that the tissue grew easily and promptly in the anterior chamber of the rabbit and in a manner analogous to malignant tumors. The placental tissue is referred to as heterologous trophoblast.

Francis M. Crage.

Landau, E. Contribution to the histology of the eye. *Ophthalmologica*, 1946, v. 112, Sept., pp. 129-134.

The author presents two diagrammatic but not very clear drawings prepared from his sections (type of eye, method of staining not stated) which are intended to show that a certain portion of the fibers of the zonule is attached to the retina. He believes that the internal limiting membrane of the retina is in reality the prolongation of the zonule of Zinn. He then describes and depicts the histologic details of the innervation of the ciliary body, without adding significantly to or deviating from present concepts.

ANNOUNCEMENTS

COURSE IN NUCLEAR PHYSICS

The University of California Medical School, in association with University Extension, University of California, announces a course in the applications of nuclear physics to the biologic and medical sciences to be given at the Medical Center in San Francisco from June 30 through July 18, 1947.

The course will consist of didactic lectures, laboratory demonstrations, and seminars for round-table discussions. It will be open to individuals in the fields of medical and biologic research. For detailed information write to: Dr. Stacy R. Mettler, Head of Postgraduate Instruction, Medical Extension, University of California Medical Center, San Francisco 22.

HEED OPHTHALMIC FOUNDATION

The Heed Ophthalmic Foundation for training eye surgeons after they have finished their residencies, established by Mr. and Mrs. Thomas Heed of Evanston, Illinois, has a fund sufficient to support three fellowships, each amounting to \$2,500 to \$3,000. A board of five ophthalmologists representing medical schools throughout the nation will handle the fellowships. Additional information and application blanks may be obtained from the secretary of the board of directors, Dr. M. Hayward Post, 520 Metropolitan Building, 508 North Grand Boulevard, St. Louis 3, Missouri.

POSTGRADUATE COURSES ANNOUNCED

The University of California Medical School announces a postgraduate course in ophthalmology to be given at the University of California Medical Center, September 15 through 19, 1947. Classes will meet daily from 8:30 A.M. to 12 noon, and from 1:30 to 5 P.M. Requests for

information and for registration are to be addressed to: Dr. Stacy R. Mettler, Head of Postgraduate Instruction, Medical Extension, University of California Medical Center, San Francisco 22.

TECHNICIANS' EXAMINATIONS

American Orthoptic Council examinations will be held in September and October, 1947. Applications on official forms must be received before July 1, 1947. Address the American Orthoptic Council, 23 East 79th Street, New York 21.

SOCIETIES

BROOKLYN'S 100TH MEETING

The 100th regular meeting of the Brooklyn Ophthalmological Society was held on April 17th at the Brooklyn Eye and Ear Hospital. The scientific program included the following papers: "Eales' Disease," Dr. Anthony J. Baranco; "Cholesterin Crystals in the Anterior Chamber," Dr. Louis Freimark; "Toxoplasmosis in Infants," Dr. Carol Schwartz; "Heterochromia Iridis," Dr. Samson Weingeist; "Binocular Single Vision with a Contact Lens after a Unilateral Cataract Extraction," Dr. John H. Bailey; "Uveitis of Undetermined Origin," Dr. James H. Inciardi; "Vessel in the Vitreous," Dr. Louis Freimark; "Calcium Soap Cyst of the Conjunctiva," Dr. Edward Saskin; "A Case of Malignant Exophthalmos," Dr. Max Fratkin; and "Unusual Melanosis of the Iris," Dr. Walter Moehle.

MEETS WITH NEUROPSYCHIATRIC SOCIETY

On April 29th, the Milwaukee Oto-Ophthalmic Society held a joint meeting with the Milwaukee Neuropsychiatric Society. The scientific program consisted of a symposium on vertigo.

PERSONALS

Dr. Parker Heath of Detroit will move to Boston about July 1, 1947, to become pathologist at the Massachusetts Eye and Ear Infirmary. Dr. Heath will also be in charge of postgraduate teaching of ophthalmology at the Harvard Medical School and will have the rank of clinical professor.

Dr. Derrick Vail has moved his offices from the Pittsfield Building to 700 North Michigan Avenue, Chicago 11, Illinois.

CYCLODIALYSIS: A FOLLOW-UP STUDY*

H. SAUL SUGAR, M.D.

Detroit

Since Heine,¹ in 1905, first described a procedure for operative detachment of the ciliary body from its insertion, the operation, which he termed cyclodialysis, has passed through various phases of popularity. Now, after more than 40 years of use in the treatment of glaucoma, reevaluation of the procedure is indicated. As part of such a reevaluation, a follow-up study of 121 cyclodialysis operations is the basis of this paper.

The first operative procedure to employ incision through the insertion of the ciliary body to form a communication between the chambers of the anterior segment and the suprachoroidea was that of Hancock² in 1861. He described six cases in which the operation was used. The procedure was modified by Heiberg³ of Christiania. In 1900, Querenghi⁴ described a procedure similar to those of Hancock and Heiberg. He called it a sclerocyclotomy or sclerochoriotomy. A transverse incision was made through the sclera and uvea behind the insertion of the ciliary body. Querenghi believed that glaucoma depended upon the lack of communication between the suprachoroidal space and the anterior chamber.

Chibret,⁵ in 1897, described a proced-

ure, which he called a sclero-cyclo-iridic puncture, for the treatment of glaucoma. He made an incision through the sclera, 3 to 4 mm. from the limbus, and guided the knife through the anterior portion of the ciliary body into the anterior chamber. When the point of the instrument appeared in the anterior chamber, it was directed backward to spear the iris which was then pulled toward the pupillary center. The procedure was repeated in 5 or 6 meridians. Eserine was used to pull the iris from the angle.

These contributions played no part in Heine's work but are cited only as evidence of the evolution of thought along this line. Heine's work was based on the observations of Fuchs and Axenfeld. Fuchs,⁶ in 1900, had found a choroidal detachment associated with low intraocular pressure after about five percent of his operations for senile cataract in otherwise normal patients. Two years later,⁷ he observed them after iridectomies for glaucoma. Axenfeld⁸ saw choroidal detachment in 10 percent of patients after iridectomy, sclerotomy, and incisions in the chamber angle. He brought up the question as to whether choroidal detachment had anything to do with the action of iridectomy in glaucoma. Demaria in Axenfeld's clinic then demonstrated, in an eye after iridectomy for glaucoma, a tear in the ciliary-body insertion which permitted communication between the suprachoroidea and anterior chamber.

*From the Illinois Eye and Ear Infirmary, University of Illinois College of Medicine, and Michael Reese Hospital, Chicago. Under a grant from the W. K. Kellogg Foundation. Presented before the Chicago Ophthalmological Society February 17, 1947.

This suggested that perhaps an artificial communication of this type would be useful in lowering intraocular pressure in glaucoma.

Heine first reported 26 operations, then a total of 56, in 1906.⁹ In 1913,¹⁰ he reported on 103 eyes on which the operation was performed. The procedure he described included a conjunctival incision, 8 to 9 mm. from the limbus, in either of the four quadrants, between the rectus muscles. The sclera was bared and an incision 2 mm. in length was made in the sclera, 4 to 5 mm. from, and concentric with, the limbus. Through this opening a spatula was inserted between the sclera and choroid into the anterior chamber, and the ciliary-body insertion was severed.

The operation was done on blind or nearly blind eyes and on various types of glaucoma in the first series of operations. Heine's reports were followed by many others. Meller¹¹ reported 48 cyclodialysis operations in 42 cases. Wernicke¹² described 67 cyclodialyses (20 of which had been in Heine's reports). Elschnig,¹³ Boldt,¹⁴ Waldstein,¹⁵ Meissner and Sattler,¹⁶ Windrath,¹⁷ and Knapp¹⁸ added many cases to the early reports. Salus¹⁹ then accumulated all the data on cyclodialysis up to 1920 for his comprehensive report. Since then, anatomic and gonioscopic data have established the *modus operandi* of cyclodialysis.

Heine's original idea was that the operation would produce a new pathway whereby aqueous would enter the supra-choroidal spaces and be slowly absorbed. Krauss,²⁰ in 1907, undertook to determine the mode of action of cyclodialysis by performing the operation on 20 eyes of rabbits and 12 eyes of cats. In all cases, a solid cicatrix formed at the operative site. The choroid and sclera became tightly adherent to the sclera. The angle of the chamber was obliterated in

all. Krauss expressed the opinion that the operation acted by reducing the pathologic accumulation of intraocular fluid by producing a more or less extensive atrophy of the uveal tract.

Other investigators, including Judin,²¹ Wichodzeff,²² Wernicke,¹² and Elsberg,²³ had results similar to those of Krauss. Wernicke pointed out, correctly, I believe, that the mode of action of the operation cannot be determined by animal experiments. This same conclusion was drawn by Elschnig,²⁴ in 1932, after Stoutenborough²⁵ and Loddoni²⁶ reported experiments on animals in which they found no atrophy of the ciliary body after cyclodialysis.

Gradle,²⁷ in 1920, was of the opinion that the reduction in intraocular pressure after cyclodialysis was due to freeing of the angle of the anterior chamber, allowing aqueous to escape through the canal of Schlemm. Beard²⁸ was of the same opinion. Apparently this theory was held by many in the United States for, in 1914, the contributor to the *American Encyclopedia of Ophthalmology*²⁹ stated that "from the few glaucomatous eyes which have as yet been examined after this operation, it is not possible to state whether the procedure can reopen the angle of the anterior chamber."

Salus,¹⁹ in his comprehensive paper, in 1920, concluded that the pressure-relieving effect of cyclodialysis depends on a partial atrophy of the ciliary body which results from obliteration of numerous arteries, and perhaps also from damage done to ciliary nerves.

In the reports on eyes enucleated after unsuccessful cyclodialysis by Heine,¹ Krauss,²⁰ Weekers,³⁰ Meller,¹¹ Wernicke,¹² Meissner and Sattler,¹⁶ Elschnig,¹³ von Grosz,³¹ and Kronfeld,³² no cleft was found. Atrophy of the ciliary body at the site of operation alone, was present in Weeker's, von Grosz's, and

Kronfeld's cases. In the others, atrophy was also present elsewhere in the ciliary body.

Elschnig had been of the opinion that the cyclodialysis operation acted through irritation of the iris and by straightening of angulated veins in the iris root, but in 1932²⁴ he had the opportunity to examine an eye of a patient who had had a successful second cyclodialysis 14 years before. He found a definite communication between the suprachoroidea and the anterior chamber. This was the first proof of Heine's original contention. It has since been amply corroborated by gonioscopic studies.

The first gonioscopic evidence of the mode of action of cyclodialysis was presented by Vannas³³ in 1935. He studied 37 cases of cyclodialysis and found patent clefts in 20 and none in 13. In 30 of the 37 there was normal tension. Four of the eyes with open clefts had been operated upon from 8 to 13 years previously.

In 1936, Barkan, Boyle, and Maisler³⁴ reported the gonioscopic data in 14 cases of primary glaucoma in which cyclodialysis had been done. In each of 11 cases in which the operation had been successful, a patent cleft was found. In three unsuccessful cases, reattachment of the ciliary body had occurred. In one of the latter, a second cyclodialysis was successful and resulted in the formation of a patent supraciliary cleft.

In 1940, I studied a series of 65 cyclodialyses on eyes with primary glaucoma and 56 cyclodialyses on eyes with secondary glaucoma following cataract operations, and found an "all-or-none" relation between success of the operation and the formation of a patent supraciliary cleft. This study was published in 1941³⁵ and 1943.³⁶ After an interval of 5 to 6 years, I have reviewed this same series of cases to determine the

validity of my original conclusions.

Let us consider first the series of 65 operations for primary glaucoma. Of the 65 cyclodialyses, 34 (52.3 percent) were successful in reducing the tension to normal. The tonometric tensions varied from 8 to 21 mm. Hg (Schiotz), averaging 15 mm. in 33 cases. In one case the tension at times reached 32 mm. Hg and so required miotics for control. In this case there was a very small patent cleft involving about 5 to 10 degrees of the circumference of the angle. In each of the 33 other cases, there were patent clefts. In the 31 cases of unsuccessful cyclodialysis, no cleft formation was revealed. In nearly all cases, there was stripping of a portion of Descemet's membrane, and in some there was reattachment of the ciliary body posterior to its original position. Thirteen of these cases were of the congestive type of glaucoma and 52 had simple glaucoma.

Since the early experiences with the cyclodialysis operation, warnings have been made repeatedly against using the operation in congestive glaucoma. Heine¹ realized this, in 1905, when he stated that the more urgent the indications the less beneficial are the results of cyclodialysis. However, the operation has been used with success in some cases of acute glaucoma, particularly where iridectomy has failed. Csillag³⁷ reported 10 successful cases including one of six-years' duration. Bangaerter and Goldmann³⁸ advised the operation in "inflammatory glaucoma" where iridectomy had been unsuccessful.

REVIEW OF CASE REPORTS

In my first report I divided the cases of cyclodialysis for congestive glaucoma into eight cases of cyclodialysis done for acute glaucoma and five for chronic congestive glaucoma. Although I now consider both groups together under acute

(narrow-angle) glaucoma, I shall consider the follow-up study on these cases under the two original subdivisions.

CASES OF ACUTE GLAUCOMA

Of the eight cases of cyclodialysis on eyes with acute glaucoma, the original observations indicated success in three and failure in five. Of the three successful cases, one experienced an acute attack nine months later, requiring further surgery. A second, operated in 1937, was still successful, with an open cleft, in 1946. The third is interesting enough to warrant description in detail.

This 27-year-old man had experienced blurring of vision, pain, and often slight injection of the right eye intermittently about twice weekly since the age of 17 years. These episodes usually occurred after seeing a motion picture or after reading, usually at night. On November 29, 1938, his pupils were dilated for refraction with 2-percent homatropine hydrobromide. The pupil of the right eye never returned to its normal diameter. Two days later he began to have pain and slight injection of the right eye. When seen four days later, the tonometric reading for the right eye was 60 mm. Hg (Schiotz). The conjunctiva was very slightly injected. Miotics were ineffective in reducing the tension to normal. A trephination done on January 11, 1939, on the right eye was unsuccessful. It was followed on February 8, 1939, by a right cyclodialysis. This was successful. The tension remained low and the cleft was visible gonioscopically. However, nearly four years later, on December 8, 1942, the right tension was elevated to 52 mm. Hg (Schiotz). On eserine therapy the tension returned to normal and has remained normal on miotics until the time of writing. The cyclodialysis cleft is open but shallow.

This case indicates the possibility of

recurrence of acute glaucoma even in a previously, successfully operated eye where this particular operation has been used. It also indicates that the cleft may again regain its patency under miotic therapy.

Of the five cases of cyclodialysis done on eyes with chronic congestive glaucoma, two were unsuccessful at the time of my first report. One of the successfully treated eyes remained normal until the present time. The second could not be followed after the year 1941. The third remained normal with an open cleft from 1939 to 1944, when a lens extraction was done. The eye subsequently became hard and even light perception was lost.

As a group, these cases of narrow-angle acute glaucoma may respond successfully to cyclodialysis; however, the cleft may be closed either by a recurrence of the original angle-blocking process or by subsequent surgery.

CASES OF SIMPLE GLAUCOMA

The remaining 52 eyes, upon which cyclodialysis for simple glaucoma was performed, represent the bulk of the follow-up series of primary glaucoma. The observations made for my first report indicated that there was no recurrence of ocular hypertension in the 28 successfully operated eyes following subsidence of all postoperative reaction. The longest interval between operation and observation was five years.

Now, after an additional six years, 11 of the 28 eyes have remained normal with open cyclodialysis clefts, and 13 could not be checked during the entire follow-up period because of death or because the patients did not return to the clinic. All of the eyes in this group of 13 had normal tension (one later required miotics for control) and an open cleft as long as they were followed.

Two other eyes were normal and had an open cleft until a cataract extraction was done, following which the glaucoma recurred. In one of these a second cyclodialysis was successful in returning the tension to normal and resulted in an open cleft. This patient was followed for only one year after the second cyclodialysis operation. Another patient had had an open but shallow cyclodialysis cleft for a year after operation but did not return to the clinic until five years later, at which time the eye was hard and the cleft closed. The one remaining eye of the series of 28 was one which continued to have a low tension, but the cyclodialysis cleft could not be seen.

As was previously pointed out,³⁵ the presence of synechias in the chamber angle before operation had little effect on the success of the operation. Twenty-four of the 65 eyes were observed preoperatively with the gonioscope. Four of these had acute glaucoma, two had chronic congestive glaucoma, and 18 had simple glaucoma. In the four eyes with acute glaucoma the angles were completely obliterated before operation. Two of the four cyclodialysis operations performed on these cases were successful. Of the two eyes with chronic congestive glaucoma, one angle was open and the other obliterated before operation. The one with the obliterated angle was normalized by cyclodialysis. The one with the open angle was not only an operative failure, but the angle was obliterated following operation except at the operative site where there was no cleft but where the angle remained open. Of the 18 eyes with glaucoma simplex which were gonioscoped preoperatively, 12 were open, four partly open, and two obliterated. Seven of the 12 open ones became normal after cyclodialysis. Two of the eyes with partly open angles became normal. Both of the eyes with obliterated angles

were successfully operated. In all of the successful cases, there were open clefts.

CASES OF SECONDARY GLAUCOMA

The series of 56 cyclodialyses in 52 eyes with secondary glaucoma occurring after cataract operation presented similar follow-up findings. At the time of the original study 23 of the 56 operations were successful (41 percent). All of these had a cyclodialysis operation in the years 1939 or 1940. Seven of the 23 eyes continued to have open cyclodialysis clefts when examined in 1946, and 10 could not be checked during the entire follow-up period, because of death or because the patients did not return to the clinic. All of these eyes had normal tension and an open cleft as long as they were followed.

In the remaining six patients, the tension became elevated during the follow-up period. In one of these the tension rose to 60 mm. Hg (Schiotz) in two years after operation. The cleft was obliterated at this time. In a second case, the tension rose to 37 mm. Hg after two years, but has usually been normal since then. However, because of corneal opacity which has developed during the interim, the presence or absence of a cleft cannot be determined. The four remaining eyes have had tonometric readings of up to 37 mm. Hg (Schiotz) but continue to have small, open, but shallow, cyclodialysis clefts.

SUMMARY

In summary, then, the original 52.3 percent of successful outcomes in cyclodialysis in primary glaucoma has been reduced to 46.1 percent after 5 to 6 years. In secondary glaucoma after cataract extraction, the percentage of success after 5 to 6 years has been reduced from 41 percent to 30.3 percent. This reduction in the percentage of successful cases would seem to indicate the need for some

modification of my conception of an "all-or-none" relationship between success of the operation and the formation of a communication between the anterior chamber and the supraciliary space.

The modification of this concept would, however, be necessary only from a gonioscopic point of view, since at times one sees what appears to be an open, shallow cleft but its extent cannot

absence of a functioning cleft can be determined gonioscopically. Then, the "all-or-none" relationship certainly holds true. The fact that ocular hypertension recurs if the cleft closes is our best clue to the *modus operandi* of the cyclodialysis operation. It indicates that atrophy of the ciliary body is not the cause of success.

I have suggested that the markedly

TABLE 1
RESPONSE TO ANTERIOR-CHAMBER PUNCTURE IN EYES WITH CYCLODIALYSIS

Patient	Type of Glaucoma	Tension before Puncture	Tension Immediately after Puncture	Tension after Puncture (mm. Hg Schiøtz)					Volume Aqueous (cc.)
		mm. Hg	(Schiøtz)	$\frac{1}{2}$ hr.	1 hr.	1 $\frac{1}{2}$ hrs.	2 hrs.	2 $\frac{1}{2}$ hrs.

8. A.B.	Simple glaucoma	30	4	18	30	40	46	40	0.19

be determined. If the cleft is shallow and extends only a very short distance back, it is usually functioning only partially. In some cases, diasceral illumination during gonioscopy is helpful in determining the extent of the cleft.

The tonometric readings should be considered in conjunction with the gonioscopic picture in drawing conclusions as to the functioning of a questionable cleft. In most cases, however, the presence or

increased vascular wall-surface area made available through the cleft permits increased osmotic absorption of aqueous. That the cyclodialysis operation is an ideal substitute for the Schlemm's canal mechanism is shown by the response to anterior-chamber puncture in eyes of eight patients, all included in the follow-up series reported herein. Four of the eight cyclodialyses were done for glaucoma due to complete anterior synechias

following operations for cataract. Three others were for simple glaucoma, and the remaining one followed unsuccessful iridectomy for acute glaucoma. The results are shown in Table 1. Only in one patient, in whom the cyclodialysis was only relatively successful, was there a typical reactive hypertension. In another, a delayed rise to 40 mm. Hg (Schiotz) was found. The chamber puncture caused no subsequent change in the intraocular pressure or the cleft in these cases.

In certain cases where the tension has been successfully reduced but no cleft can be seen, failure to determine the cause of success is disconcerting. However, one may find the cause in some instances, not in others. In one instance, I observed subconjunctival filtration at the site of the scleral incision where choroid was incarcerated in the wound. In another the cleft could not be seen because an anterior synechia had formed a bridge between the iris and cornea and was located like a screen in front of the cleft. Only an opening at one side could be seen; so the presence of a patent cleft could only be inferred from the fact that the tension continued low.

One must, of course, be especially careful when observing the tension during the first six weeks after operation. During this period, even with no visible cleft, the tension may be normal. The eyes are usually somewhat injected and soft because of the reactive vasodilatation. When the eyes pale, the tension in such cases usually goes up.

In a study³⁵ to determine the length of time which may elapse after operation before one can judge the success or failure of cyclodialysis, I ascertained the time between operation and the first occurrence of tension above 28 mm. Hg (Schiotz) in 19 eyes with simple glaucoma, in which the cyclodialysis clefts had closed and the tension had become

elevated. For the eyes with normal tensions at the time of the first return visit, the interval between operation and recurrence of hypertension varied from 1 to 16 weeks, averaging 5.8 weeks.

Closure of a previously open and functioning cyclodialysis cleft, as a result of subsequent cataract extraction, is to be expected but does not always occur. In one of the successfully operated cases in this series, a cyclodialysis was done in January, 1938, after an unsuccessful trephination. The cleft remained open, and the tension continued to be normal. In May, 1939, a right extracapsular lens extraction was done. The cleft remained open subsequently and was open when last seen in June, 1946. However, on several occasions since 1944, there have been slight increases in tension to around 30 mm. Hg (Schiotz). The pocket is unquestionably decreasing in extent, but this cannot be determined gonioscopically. A second patient, not of this series, had had an iridectomy performed on the left eye in 1935. This was followed by a trephination in 1937, and later by a cyclodialysis during the same year. A patent cyclodialysis cleft was visible. An intracapsular lens extraction was done in February, 1946. The tension has remained normal since then. The cyclodialysis cleft has remained patent.

COMPLICATIONS OF CYCLODIALYSIS

The complications of the cyclodialysis operation may be divided into early and late groups. The early complications include surgical complications such as failure to cut all the scleral fibers in making the incision, episcleral hemorrhage, hemorrhages into the anterior chamber and vitreous, lacerations of Descemet's membrane, iridodialysis, subluxation of the lens, lens injury,^{19, 41, 43, 45} perforation into the vitreous, and iridocyclitis.^{19, 43} The late complications are hypotony,⁴⁰

retinal detachment,³⁰ opacities of the cornea, ecstasia of the operative scar, cataract formation, changes in refraction,^{19, 41, 43, 45} and closure of a previously patent cleft.

EARLY COMPLICATIONS

Of the early complications, the hemorrhages and lacerations of Descemet's membrane are the only ones which do not depend entirely on the operator's skill and care. McPherson⁴⁰ found anterior-chamber hemorrhages in 52.9 percent of 140 eyes at the time of operation, and an additional 6.5 percent at the time of the first dressing. Vitreous hemorrhages occurred in 5.7 percent of the cases he reported. He also found lacerations of Descemet's membrane in 5 percent. These lacerations rarely interfere with visual or tonometric results. The intraocular hemorrhages are one of the chief causes of closure of well-formed cyclodialysis clefts. The hemorrhages may be from the ciliary body or iris; or from vessels that pass from the ciliary body to the sclera which the spatula will sever, if these vessels are present. For this reason, and in order to prevent severe pain from the pulling on nerve loops, the horizontal meridian should be particularly avoided during the operation.

I reviewed the hospital records of all the patients in the follow-up series discussed herein to determine the relation between the incidence of hyphemia and the successful outcome of the operation (table 2). The incidence was probably greater than stated, especially since inadequate notes were found in some cases. Hyphemia occurred in 18 (52.9 percent) of the successful primary glaucoma cases and in 22 (70.9 percent) of the unsuccessful ones. In the secondary glaucoma cases following cataract operations, 14 (60.8 percent) of the successful ones, and 27 (81.8 percent) of the

unsuccessful ones had hyphemia. It is apparent that hyphemia does not preclude success, but it is also true that lack of success is associated with a greater incidence of hyphemia. In the total of 121 cyclodialyses, hyphemia occurred in 56.1 percent of the successful cases and 76.5 percent of the unsuccessful ones. The incidence of fresh hemorrhages first occurring from 2 to 11 days postoperatively is also somewhat higher in the unsuccessful cases than in the successful ones.

In order to avoid unnecessary trauma and a too large cleft, which might result in hypotony, I formerly advocated^{35, 36} a decrease in the extent of sweep of the cyclodialysis spatula. However, I have now reverted to a sweep of 120 degrees, still avoiding the horizontal meridian. The inverse cyclodialysis of Blaskovics⁴⁶ is preferable since it tends to reduce trauma.* When the eye is aphakic, the operation is done below. In nonaphakic eyes, the upper quadrants are preferred, in order to keep any hyphemia away from the cleft. When the cleft is made below, the patient is kept lying on one side after the operation.

In order to prevent postoperative closure of the cyclodialysis cleft, the use of physostigmine immediately after the operation and in the early postoperative period is recommended. In addition, I have found air injection helpful. After completing the cyclodialysis sweep, a blunt lacrimal needle attached to a syringe is inserted through the scleral in-

* The Blaskovics operation consists of a horizontal incision in the conjunctiva and Tenon's capsule at the level of the insertion of the superior rectus tendon, a vertical incision in the sclera extending 4 mm. from the insertion of that muscle toward the limbus, with the perforation 1.5 mm. long about 7 mm. from the limbus, and a sweep of 110-115 degrees with Elschnig's spatula. The insertion of the ciliary body is thus severed from behind forward. This operation may be applied to any meridian.

cision into the supraciliary cleft up to the chamber angle, and any aqueous present is withdrawn. The syringe is then partly filled with air which is then injected into the anterior chamber.

One may prefer to do both the dialysis operation and the air injection through the spatula devised by Randolph⁴⁷ who was the first to use air injection after cyclodialysis. After air injection, the cleft can usually be seen directly through the cornea. The air bubble pushes the iris and ciliary body backward, thus tending to keep the cleft open. The bubble persists for four days with usually some remnant visible on the fifth or sixth days. I have been unable to evaluate separately the effect of each factor in the operation in my own cases. However, the combination of factors has certainly improved my own results.

LATE COMPLICATIONS

The late complications with which we are most concerned are cataract formation and changes in refraction in nonaphakic eyes, and closure of a previously patent cleft in both nonaphakic and aphakic eyes.

Cataract formation after cyclodialysis is probably related to hypotony.⁵⁴ Stein⁴² reported 20 instances of cataract, which occurred in 24 percent of the hypotonic eyes in the group of private patients he studied. Statistics concerning cataract formation are difficult to evaluate because one cannot be certain that late cataract formation would not have occurred if the operation had not been done. Many of these cataracts probably result from a progression of previously incipient opacities. Early cataract formation should probably be attributed to operative trauma. Salus noted posterior subcapsular opacities which he considered characteristic and found mostly in hypotonic eyes. He reported 19 instances of

cataract formation in 350 eyes.

The changes in refraction after cyclodialysis have been discussed by Salus,¹⁹ Stein,⁴² and Bunge.⁴³ Salus found an increase in refraction in 43 instances and a decrease of refraction, 11 times in 350 eyes. Bunge found increased refraction amounting to from 1 to 5 diopters in 13 eyes of patients with simple and chronic congestive glaucoma. Stein reported an increase in refraction of 0.5 to 4 diopters in 24 cases and a decrease in refraction, three times. The increased refraction was in the nature of a decrease in hyperopia in 12 cases, an increase in myopia in eight, and a change from hyperopia to myopia in four. He believed the change was due to the stretching of the zonule.

I reviewed the records of a series of 48 operated eyes and 33 unoperated eyes with primary glaucoma to determine the amount of refractive change after cyclodialysis, as compared with the change after other operations and with refractive change in unoperated glaucomatous eyes. The results are shown in Chart 1.

The 48 operated eyes consisted of 14 following iridectomy, 12 after cyclodialysis, 11 after trephination, and 11 after iridencleisis. These patients were from the private practice of Dr. Harry S. Gradle and Dr. S. J. Meyer. All of the operated cases were selected on the basis of preoperative visual acuity of 20/25 or better and not less than 20/40, during the first year after operation. Only patients who had recently been refracted were included.

As for the 11 iridencleisis cases, the short one-year period of follow-up was due to the fact that most of the operations of this type were relatively recent. In the case of cyclodialysis, the one-year follow-up period was due in part to cataract formation and in part to the fact that secondary operations were relatively frequent so the cases could no

longer be included in this study.

In all types of operation, an average increase of refraction of 0.37 to 0.75 diopters occurred during the interval between the preoperative examination and the first postoperative examination.

In every group the average refraction

ination one year after operation in the cyclodialysis group. In the trephination group, the greatest postoperative change occurred in this small series.

Of the 12 cyclodialysis cases, two decreased slightly in refraction—in one case, only 0.25 diopters; in the other, 0.50 di-

Chart 1 (Sugar). A comparison of cyclodialyses, trephinations, and iridencleises at the Illinois Eye and Ear Infirmary, Chicago, 1931 to 1945.

continued to increase as time passed. In the iridectomy group the change was least of all, reaching only 1.0 diopter after six years. The increase of 2.5 diopters more after eight years and of 4.75 more 10 years after operation must be considered as unrelated to the iridectomy procedure itself. There was relatively little difference between the first postoperative examination and the exam-

opters. One showed no change. The nine remaining cases increased in refraction up to 2.5 diopters. Nine of the 12 had been hyperopic. Three of these became myopic.

Closure of a previously patent cyclodialysis cleft is one of the most serious of the late complications. It has been the cause of most of the objections to the operation. The duration of successful re-

sults after cyclodialysis has been the subject of several papers.⁴²⁻⁴⁴ Stein⁴² found, in a total of 120 cyclodialyses which had been done on private patients of Elschmig, that an average of 72 percent of simple glaucoma and 70 percent of chronic uncompensated cases had lasting success. In one case success had lasted

sults—one case, 11 years; 3 over 6 years; 7 between 1½ and 4 years; and 2 were observed less than one year. In the second group, that of secondary glaucoma of various types, not including postcataract glaucoma, there were seven cases. In one, the tension remained normal for 13 years. The third group consisted of 34

Chart 2 (Sugar). A comparison of cyclodialyses, trephinations, and iridencleises at the Michael Reese Hospital, Chicago, 1926 to 1945.

20 years. Of 393 cyclodialyses in clinic patients, he reported success in 79 percent of simple glaucoma cases and 68.8 percent of uncompensated glaucoma cases. Bunge⁴³ found 68.9 percent success in simple and congestive glaucoma.

Hausmann⁴⁴ divided her cases into five groups. In the first group of 21 cases of postcataract glaucoma, 13 had lasting re-

sults of primary chronic glaucoma in which a cyclodialysis was the only operation. Eight of these were normal over a 4-year period. Two of the latter had normal tension and vision for 14 years. Seven were normal up to three years, and 12 were normal during an observation period of less than a year. The fourth group consisted of 22 cases in

which cyclodialysis was followed by other operations. Thirteen of these cases were helped. The fifth group was made up of 21 cases in which cyclodialysis followed other operations. In one case the tension remained normal for 14 years, and, in another, 9 years.

cent of all glaucoma operations in 1923, remained about 50 percent, then rose to over 60 percent in 1933. Trephinations during the same period, 1918 to 1933, fell from 40 percent of all glaucoma operations to nearly zero in 1923, rose slightly to 10 percent in 1939, and re-

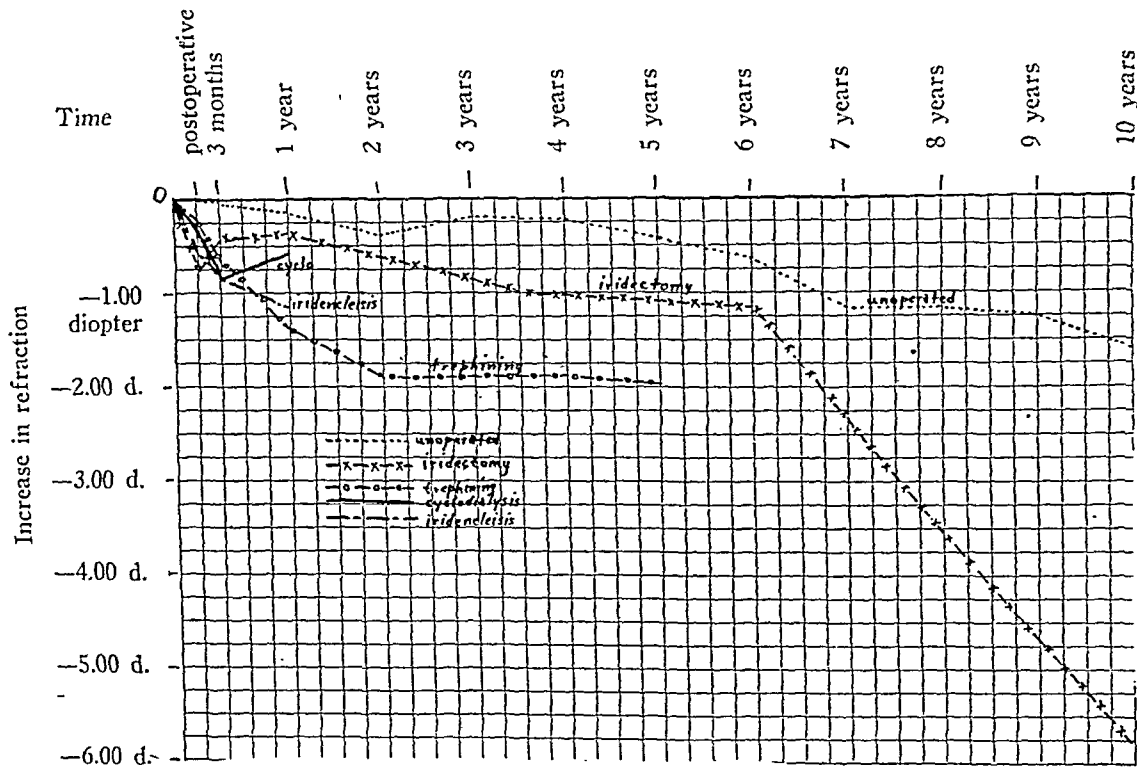

Chart 3 (Sugar). Refractive increase (averages) in unoperated glaucomatous eyes and after various operations for glaucoma.

Louhala and Teräskeli⁵⁴ reported a preliminary good result in 72 percent of cyclodialyses for simple glaucoma. After a period of 1 to 10 years of follow-up, good results were found in only 52 percent of the follow-up cases.

The frequency of employment of cyclodialysis as compared to other operations in the treatment of glaucoma gives an indication of the opinion held generally as to its efficacy. Von Grosz's³⁸ statistics concerning the Budapest Eye Clinic indicate that the cyclodialysis operation rose from zero in 1918 to over 50 per-

cent at about 10 percent until 1943. Iridectomy had been the most frequent in proportion to the increased frequency of cyclodialysis.

Bunge cites similar statistics from other European authors of the period, 1918 to 1931. Similar but more recent results from the University of Helsinki are worthy of mention. Louhala and Teräskeli reported that, until 1930, trephination was the most common glaucoma operation in Finland. Iridencleisis came next in frequency. Between 1931 and 1942, cyclodialysis was the most frequent

operation (206 cyclodialyses in a total of 520 operations for glaucoma). Iridencleisis came next (165), then iridectomy (140), and lastly, trephination (5).

A review of the number of cyclodialysis operations compared to trephinations and iris-inclusion operations performed during the past 15 to 20 years at the Illinois Eye and Ear Infirmary, a state institution where no private work is done, and at Michael Reese Hospital, a private institutions where the eye patients were in large part from the practice of Dr. H. S. Gradle, gives an indication of the trends in glaucoma surgery in Chicago. The results of this review are shown in Charts 2 and 3. It would be interesting to compare these results with those of other institutions, especially those elsewhere in the United States.

It is worth noting that since 1940, the iris-inclusion operations have comprised about 60 percent of glaucoma operations (excluding iridectomy) in both institutions. In 1945, cyclodialysis comprised slightly over 30 percent of these glaucoma operations in both places. The graphs indicate considerable variation, however, in the trends between each institution. This was noted also among the six individual services of the Infirmary, indicating the importance of personal preference by each surgeon for a particular procedure.

The indications for cyclodialysis have changed remarkably during the period in which the operation has been in use. In 1914, the contributor to the *American Encyclopedia of Ophthalmology* wrote:²⁹ "The real indication for it (the cyclodialysis operation) is the impossibility of performing iridectomy from the presence of very high intraocular pressure and absolute glaucoma which has progressed far."

Meller⁴⁸ early preferred cyclodialysis to iridectomy in certain cases because it

was decidedly less dangerous. The procedure was considered to be indicated in very hard eyes with very shallow chambers; in hemorrhagic glaucoma; and in those cases in which the fellow eye had been lost through malignant glaucoma or through severe hemorrhage following iridectomy; in aphakic eyes with fluid vitreous; and in hydrophthalmic eyes.

Elschnig considered cyclodialysis a valuable addition, especially for simple glaucoma, hydrophthalmos, secondary glaucoma, or when iridectomy could not be done or had failed. Waldstein¹⁵ favored its use in simple glaucoma, and in secondary glaucoma due to luxated or subluxated lenses. In 1922, Elliot⁴⁹ considered cyclodialysis to have gone out of favor in hydrophthalmos.

In 1924, Fuchs⁵⁰ considered that the operation should be reserved for cases in which other operations have failed or proved fatal to the other eye, or cases in which iridectomy is difficult or dangerous. Meller,⁵¹ in 1923, listed the indications for cyclodialysis as: (1) the early stages of glaucoma; (2) acute glaucoma in which iridectomy is difficult and dangerous; (3) patients who have lost one eye from malignant glaucoma or from severe hemorrhage after iridectomy, and also in old, restless people; (4) secondary glaucoma, including that due to anterior synechia in which the tension increased after cataract extraction.

Von Grosz,⁵² in 1932, believed the indication for cyclodialysis to be "chronic inflammatory glaucoma." Gradle,²⁷ in 1920, considered the operation distinctly contraindicated in acute glaucoma of an exudative or inflammatory type, and in cases where immediate operation is desirable. He later,⁵³ in 1931, considered the indications for cyclodialysis to be: (1) simple noninflammatory glaucoma of the type just beyond the control of miotics; (2) simple glaucoma with high intraocu-

lar pressure and a visual-field defect extending to within 10 degrees or less of the fixation point; and (3) after unsuccessful but technically correct iridectomy.

McPherson⁴⁰ in his recent report from the Wilmer Institute advocated Gradle's dictum regarding the use of cyclodialysis in chronic simple glaucoma without inflammatory reaction. However, his report of 42-percent successful results in 45 cases of chronic simple glaucoma and in 35.9 percent of 39 cases following cataract extraction, which is similar to the results in my own series, does not appear to be as good as the reports made for trephination and iridencleisis for simple glaucoma.

Thus, although successful cyclodialysis in simple glaucoma gives an ideal physiologic result, theoretically, the percent of success is less than after the filtering operations. There are two exclusive indications for the operation: (1) glaucoma in aphakic eyes, no matter whether simple glaucoma, obstructive glaucoma due to complete anterior synechias, resulting from cataract operation, or glaucoma capsulare; and (2) secondary glaucoma due to posterior subluxation of the crystalline lens. In addition cyclodialysis may be successful in certain instances of narrow-angle glaucoma where a previous iridectomy has been unsuccessful. In simple glaucoma, cyclodialysis may be used, even with only about 45-percent success, since the operation does not carry with it the danger of late infection and since it may be repeated without damage to the integrity of the eye.

CONCLUSIONS

1. A relatively small number of successful cyclodialysis operations, after varying periods of time, become failures or relative failures. The original 47.1 percent of success in a total of 121 cyclo-

dialyses of all kinds, observed up to five years, was reduced to 38.8 percent after an additional six-year period.

2. The "all-or-none" relationship between success of the cyclodialysis operation and the formation of a supraciliary cleft is a fact, but must be modified from a gonioscopic view, since the depth of a cleft cannot always be determined by this technique.

3. Cyclodialysis operations may remain successful in some instances, in spite of subsequent cataract surgery.

4. An increase of refraction usually occurs after cyclodialysis, as it does following other glaucoma operations.

5. The trend in the use of the cyclodialysis operation in two Chicago hospitals has become somewhat less frequent in recent years, particularly in comparison to the recent increase in the use of the iridencleisis operation.

6. The two exclusive indications for cyclodialysis are: (1) glaucoma in aphakic eyes; and (2) secondary glaucoma due to posterior subluxation of the crystalline lens. In addition, the operation may be successful in cases of shallow-angle glaucoma where a previous iridectomy has been unsuccessful. In simple glaucoma, the percentage of success is relatively low, but the operation has certain advantages.

7. The percentage of success in the formation of clefts may be improved by separating the ciliary body from the scleral spur along a third of the angle circumference, preferably by the use of the Blaskovics technique. The use of eserine and the keeping of the patient in such a position after operation that any hyphemia will not settle in the cleft are advocated. The injection of air into the anterior chamber through the scleral incision by way of a lacrimal needle is suggested as an additional aid.

INVERSE CYCLODIALYSIS*

ROBERT N. SHAFFER, M.D.
San Francisco

The success of a cyclodialysis operation in controlling glaucoma is entirely dependent upon the production of a permanent cleft at the anterior-chamber angle through which aqueous can enter the suprachoroidal space. This fact was demonstrated microscopically by Elschmig,¹ in 1932, and confirmed gonioscopically, in 1936, by Barkan, Boyle, and Maisler,² and by Clarke,³ in 1941. Any variation in technique is well worth while, if it makes more certain the production of this cleft and the prevention of hemorrhage. Such a variation is the inverse cyclodialysis of Blaskovics.

The operation of cyclodialysis was introduced in 1905 by Heine⁴ and popularized in 1920 by Salus,⁵ using the same fundamental procedure as is now employed routinely. Mauksch⁶ has added suprachoroidal iridotaxis to the routine cyclodialysis. Troncoso⁷ has suggested the use of magnesium implants which, by producing hydrogen bubbles in the cleft, help to keep it open. Wootton⁸ combined an iridectomy with the dialysis. An increasing number of surgeons are introducing air into the anterior chamber upon the completion of the cyclodialysis. The inverse maneuver is a fundamental change in technique devised by Blaskovics⁹ and described by him in Szemeszet, in 1935. One other article by Pereira¹⁰ in the Spanish literature reports using the operation successfully in one case. Other than this, no mention of the technique has been found in the literature, although an occasional surgeon in this country has used the method.

* From the Division of Ophthalmology, University of California Medical School.

EXPERIMENTAL PROCEDURE

In 1944, Dr. Owen Dickson and I conducted a series of animal experiments, using dogs, cats, rabbits, and monkeys, to determine the effect of air injection into the anterior chamber following cyclodialysis. A cyclodialysis in a dog is complicated by extensive hemorrhage from the scleral incision. In order to control bleeding, a radial scleral incision was tried rather than the usual tangential variety. Since this incision paralleled the scleral blood vessels, there was a material decrease in bleeding.

Because it was found difficult to introduce an Elschmig spatula directly into the anterior chamber through the radial incision, the inverse technique was tried. The spatula was inserted laterally between the sclera and the pars plana of the ciliary body to the full extent of the spatula. The blade was then swept forward into the anterior chamber, effecting the separation in a direction opposite to that of the usual method; hence, the term, "inverse cyclodialysis."

In dogs, cats, and monkeys, the dialysis could be done more easily and with less force being applied to the spatula than in the routine type. There also seemed to be less anterior-chamber hemorrhage by this approach, even when the scleral incision was made tangentially.

In rabbits, a cyclodialysis is difficult to accomplish because of the friability of the iris and its intimate attachment to the sclera. Almost invariably the tip of the dialysing spatula appeared behind the iris when the routine approach was used. However, with care a cyclodialysis could be performed by the inverse approach.

Upon checking the microscopic anatomy of the ciliary body and its attachment to the sclera in glaucomatous and nonglaucomatous human eyes, it seemed that the inverse approach was a logical one. As shown in Figures 1 and 2, the fibers of the ciliary body run forward and are practically continuous with the trabecular fibers overlying Schlemm's canal. Part of the scleral spur actually lies in front of the canal. The angle of the anterior chamber does not end at the point of ciliary-body attachment at the scleral spur, but actually points into the ciliary body itself. Consequently, when an Elschnig spatula is pressed into the angle in the routine manner, it has to tear through anterior ciliary body, in some instances, before reaching the suprachoroidal space. This trauma would cause increased bleeding. A clot lying between the raw surfaces of a damaged ciliary body would encourage fibroblastic invasion which would tend to seal up the intended cleft. Thus, even in eyes without anterior synechiae, the inverse approach seems to follow a natural cleavage plane.

Fig. 1 (Shaffer). Normal open angle. AC, Anterior chamber; C, Schlemm's canal; SS, Scleral spur; SC, Suprachoroidal space.

This should help to dialyse the ciliary body from the scleral spur at the trabeculum with a minimum of trauma.

In the eyes with extensive anterior

synechiae (fig. 3), such as occur in late glaucomas and particularly in postcataract glaucomas, the chances for an atraumatic and successful dialysis by the usual

Fig. 2 (Shaffer). Normal open angle showing how easily anterior ciliary body can be torn by dialysing spatula approaching suprachoroidal space from anterior chamber. AC, Anterior chamber; C, Schlemm's canal; SS, Scleral spur; SC, Suprachoroidal space.

method seem to be definitely less. If, as the spatula is swept toward the angle, it encounters a firm synechia, there is a tendency for the iris to fold back in front of the spatula toward the posterior chamber. This might result in an iridodialysis, or merely in a failure to produce a true cleft. By using the inverse method, it would seem probable that the blade of the spatula would follow the line of cleavage between the synechiae and the cornea. One would reasonably expect that there would be less tendency to transfix the iris or to injure Descemet's membrane if the side-sweep of the spatula were employed than if its tip were thrust through the synechiae into the anterior chamber, as in the routine approach.

CASE REPORTS

Case 1. Our first opportunity to use the inverse method in operating on a human being was in a highly unfavorable case seen in January, 1945. This was a

cataract patient with diabetes, which was difficult to control in the hospital and which was frequently uncontrolled under home conditions. She had had an extracapsular cataract extraction with full iridectomy and corneoscleral sutures. An anterior chamber had formed the first day but was collapsed on the second. Efforts to demonstrate a fistula along the incision

tip of a spatula past so broad a synechia to the pupillary area; so the inverse method was tried. The technique was not difficult, and part of the iris was loosened from the cornea. The tension was not controlled, however, and the inverse procedure was repeated. This time, as the spatula swept into the pupillary area, the iris could be seen dropping back into po-

Fig. 3 (Shaffer). Angle showing anterior synechiae. AC, anterior chamber; AS, anterior synechia; C, Schlemm's canal; SC, Suprachoroidal space.

line were unsuccessful. Aqueous could be seen between the cornea and the vitreous face in the pupillary area and behind the iris, but the entire extent of the iris was adherent to the cornea. Air injection between the iris and the cornea failed to free the adhesions. As one would expect, the tension was greatly elevated.

Six weeks after the cataract operation, it was decided to attempt a cyclodialysis. It seemed almost impossible to work the

situation. The anterior chamber was reformed and has persisted. Although the tension remained at 30 mm. Hg (Schiotz), further surgery was not considered because the eye was essentially blind. After waiting several months, this patient's second eye was operated upon for cataract. The operation was uneventful; the incision was carefully sutured; a large air bubble was instilled into the anterior chamber. Again the chamber was shal-

low the first postoperative day, and completely collapsed the second. The iris remained against the cornea even though the vitreous face was pressed back in the pupillary area by aqueous. At the end of one week, an inverse cyclodialysis was performed without difficulty; a large air bubble was injected into the anterior chamber, and a posterior sclerotomy was performed to reduce posterior-chamber pressure. The chamber was restored, and the intraocular pressure remained in the normal zone.

Case 2 was a patient with narrow-angle glaucoma who had had two previous cyclodialyses performed in the usual way. Very small and shallow clefts had been produced. The first one had held the tension at normal for only five months, the second for a year. An inverse dialysis, performed in an untraumatized portion of the angle, produced a large cleft which is functioning well at the present time.

Cases 3 and 4 were patients with wide-angle glaucoma. One was secondary to a subluxated lens; the other to a glaucoma capsulare. In these we combined the inverse with the standard routine, sweeping inversely from the scleral side into the chamber, then completing the other half into the suprachoroidal space in the routine direction. The success achieved in these two cases completed our conversion to the Blaskovics' procedure; for, in both of these cases, the part dialysed routinely had no cleft whatever, and the part done inversely had beautiful clefts!

By July 1, 1946, 21 cases had been operated by the inverse method, and with one exception we have had no reason to question its worth. This one exception was a case of wide-angle, or chronic simple, glaucoma in a man, 47 years of age. The tension, 30 to 40 mm. Hg (Schiotz) in one eye, could not be controlled by miotics. His seemed an ideal case for cyclodialysis. This was done by

the inverse method with a minimum of trauma and bleeding. The following day the eye was stony hard. The conjunctiva was so edematous as to suggest a posterior venous thrombosis. Tension remained over 70 mm. Hg (Schiotz) for two weeks despite the most energetic measures short of surgery. Gradually tension dropped back to 30 mm., leaving a mid-dilated, fixed pupil, corrected vision of 20/30, moderate field loss, a normal fundus, and an unsolved problem. The operative site showed no cleft gonioscopically. Explanation for the failure is lacking.

PRESENT CYCLODIALYSIS TECHNIQUE

1. ANESTHESIA

Premedication consists of nembutal (0.1 gm.) given the night before surgery and repeated the morning of surgery. Usually, morphine sulfate (10 to 15 mg.) is given hypodermically when the patient is called to surgery. Eserine (0.5 percent) is instilled twice before starting the anesthesia in order to keep the pupil miotic. Pontocaine (0.5 percent) is dropped into the eye at 3-minute intervals, 5 times. Meanwhile a Van Lint akinesis, and retrobulbar and subconjunctival injections of 2-percent novocaine and 1:20,000 adrenalin, are given. The retrobulbar injection of 1.5 cc. is used 30 minutes before starting surgery to effect maximum softening of the eye. It also frequently deepens the anterior chamber, making the dialysis easier. Complete anesthesia is essential. If regional block is ineffective, general anesthesia is indicated.

2. SELECTION OF OPERATIVE SITE

That portion of the angle is chosen for cyclodialysis which gonioscopy has shown to be most widely open and most free of anterior synechiae and blood vessels. This permits the dialysis to be done

with a minimum of trauma and bleeding. If there is no choice, the upper temporal quadrant is chosen because of ease of access and because the patient can sit up postoperatively to allow any hemorrhage to run out of the cleft into the bottom of the anterior chamber. Authors usually suggest that the 180-degree meridian be avoided to prevent bleeding from the long posterior ciliary arteries. However, since

Fig. 4 (Shaffer). Conjunctival incision is 8 mm. from limbus. Scleral incision is 5 mm. from limbus. Traction suture in place.

these enter the posterior portion of the ciliary body, the dialysing spatula should not injure them. We have not seen increased bleeding from this area. The major portion of the dialysis should lie in the quadrant between the muscles to avoid the anterior ciliary arteries, which perforate the sclera 2 to 3 mm. anterior to the tendinous insertions.

3. INCISIONS

A 10-mm. conjunctival incision is made with scissors, 8 mm. from the limbus and parallel to it (fig. 4). The scleral incision should be 4 to 5 mm. from the limbus. It can be made with a No. 15 Bard-Parker blade, or with a keratome. The external incision should measure 4 mm. with a 1.5- to 2-mm. opening into the

suprachoroidal space. It can be placed either radially, as suggested by Blaskovics,⁹ or tangentially in the routine manner.

Since the radial incision has the advantage of running with the scleral fibers, there is less tendency for the wound to gape. It also parallels the blood vessels and reduces hemorrhagic tendencies. If there is any bevel to this radial incision, however, it becomes impossible to reintroduce the spatula under the scleral shelf should a second half-sweep be desired. Therefore, the radial incision should be perpendicular to the sclera, and the tangential one should be bevelled slightly toward the cornea. To avoid a ragged incision through which the introduction of a spatula is difficult, the cutting instrument should be held in the same plane at all times, and the perforation should be made in as few strokes as is consistent with safety. If any severe scleral bleeding occurs, it must be controlled by high-frequency coagulation, or by actual cautery. When the sclera has been completely incised, it is possible to depress one lip of the scleral wound by pressing upon it. The black ciliary pigment can then be seen in the depths of the incision.

4. FIXATION

If a double inverse dialysis is contemplated, the tangential incision is usually chosen because of the greater ease of manipulation. When the scleral cut is half completed, a 4-0 Anacap suture is passed through the corneal lip of the incision. If the first bite is not a strong one, a second turn through the sclera is made. This then serves as a traction suture in making the dialysis. If a radial incision is made, contemplating only half of a dialysis, the traction suture is placed in the lip on the side of the contemplated dialysis. Although Elschnig forceps can be used for fixation, they have an unhappy faculty of

loosening their grip at a critical moment in the operation.

5. THE DIALYSIS

After the perforating incision is completed, the Elschnig spatula is placed in a horizontal position with the tip resting on one lip of the wound. When this is depressed, the ciliary body is pressed away from the under surface of the opposite scleral lip, and the spatula can be introduced with ease. If there is any re-

Fig. 6 (Shaffer). Elschnig spatula in suprachoroidal space parallel to limbus.

Fig. 5 (Shaffer). Introduction of Elschnig spatula into suprachoroidal space. Traction suture lifting anterior scleral lip.

depressed. When the blade is completely out of sight under the sclera, it is slowly rotated (fig. 7) toward the anterior chamber. Resistance is felt when the scleral spur is reached. The operator should accomplish the dialysis with great care and deliberation. As the tip and side of the blade come into view at the angle, one must avoid pressing it upward against the cornea, or backward against the stroma of the iris. Rotation is continued until the blade is in the middle of the anterior chamber. It is then quickly

Fig. 7 (Shaffer). Rotation of spatula past attachment of ciliary body to scleral spur into the anterior chamber.

sistance, it is because scleral strands remain at the depths of the wound, and these must be severed. As in Figures 5 and 6, the blade of the spatula is pressed gently forward along the inner surface of the sclera parallel to the limbus. Small side-to-side movements are made as the blade is advanced, both to avoid wrinkling the pars plana of the ciliary body in front of the spatula and to keep track of the tip of the blade which can usually be seen through the sclera. When the blade is introduced half way, considerable resistance is sometimes encountered. This means that the operator is holding the spatula too firmly against the inner sclera, and that the point must be slightly

Fig. 8 (Shaffer). Completion of one half the dialysis. Spatula is withdrawn in this position.

removed (fig. 8). A second spatula can then be inserted in the opposite direction (fig. 9), to double the size of the cyclo-dialysis, if desired.

Fig. 9 (Shaffer). Introduction of the Elschnig spatula in the opposite direction. It is swept into the anterior chamber as in Figures 7 and 8.

6. AIR INJECTION

As pointed out by Hughes and Cole,¹¹ air in the anterior chamber is well tolerated. We have been using air injections routinely following cyclodialysis for over

two years. We have been impressed by the arrest of hemorrhage as soon as the air is introduced into the anterior chamber. Doubtless this is due to the restoration of intraocular pressure, which reduces capillary bleeding. Filtered air is placed in a small Luer or anterior-chamber irrigator to which is attached a slightly flattened lacrimal needle (fig. 10), bent to correspond to the curve of the Elschnig spatula, but only 6 mm. in length. This is introduced as promptly as

Fig. 10 (Shaffer). Injection of air into anterior chamber with a 2-cc. Luer irrigator and a lacrimal needle.

possible after the dialysis and sufficient air is injected to restore the normal depth of the anterior chamber. In one of our cases the chamber was quite shallow, and in our enthusiasm to ensure an open cleft, too much air was instilled. This produced a deep chamber and increased the intraocular pressure. When the needle was removed, the tangential incision gaped slightly, and a small choroidal herniation appeared, thinned out, and was followed by a small bead of vitreous. Fortunately, a good cleft and a fine functional result were obtained, despite the accident.

7. CLOSURE

The conjunctiva is closed with interrupted black silk sutures (fig. 11), which can be removed on the fifth postoperative day.

8. POSTOPERATIVE ORDERS

The patient's head is held with the dialysed portion of the eye upward. The air in the anterior chamber then gravitates up into the cleft, helping to hold it open. At the same time, any blood in the cleft can run out into the dependent part of the chamber.

Medication is used as indicated. If the pupil is large, it is constricted to pull the iris away from the cleft. If it is small, it must be dilated briefly on the second or third day with 2.5-percent neosynephrin to avoid permanent posterior synechiae. Such synechiae must be guarded against for several weeks, as there is almost always a moderate postoperative iritis. In rare instances, this may persist for months.

Gonioscopy, done as soon as the eye is quiet enough to tolerate the procedure, yields information as to the safety of proceeding with mydriatic therapy if an iritis is present. A definite prognosis can

Fig. 11 (Shaffer). Air bubble in the anterior chamber. Conjunctiva closed with black-silk suture.

usually be given in two or three weeks. If the cleft is shallow or short in extent, the outcome may be doubtful, but a wide, open cleft usually means success. When there is no cleft, the operation has been a definite failure.

STATISTICS

Our series of 21 inverse cyclodialyses is too small to be of any great statistical value, but each case has been carefully classified and has been followed for six months to two years postoperatively, so

TABLE 1
STATISTICS IN VARIOUS TYPES OF GLAUCOMA

	Number of Operations	Successes	Percent

Total			
Routine	46	24	52
Inverse	21	16	76

that the prognosis is quite definite. As a control, 46 similarly classified glaucoma cases, operated by the routine technique, have been used. A cyclodialysis which reduced the tension below 25 mm. Hg (Schiøtz) for one year, or for six months if a good cleft was visible gonioscopically, has arbitrarily been classed as a success. To date none of the inverse group which has been classed as a success has had a secondary rise in tension.

Blaskovics reported a total of 53 inverse cyclodialyses and compared them statistically to 53 similar cases operated by the routine Heine-Elschnig technique. He states that but few of his patients returned for follow-up examinations. His immediate statistics record successful normalization of tension in 67 percent of cases done by his inverse technique, as compared to 48.3 percent successfully operated by the other method. As in our experience, he found the dialysis to be

more easily performed, with fewer post-operative complications, such as bleeding, tears in Descemet's membrane, and iridodialysis.

SUMMARY

Inverse cyclodialysis is the method advocated by Blaskovics of effecting a dialysis by sweeping the Elschnig spatula from the suprachoroidal space into the anterior chamber. Its use, together with air injection, seems to offer a safer and more successful procedure in all cases requiring cyclodialysis. It is of particular value in glaucoma secondary to cataract surgery. Gonioscopic control of the site of operation is essential, if blood vessels and synechiae in the angle, which needlessly add to the complications, are to be avoided. The author's modifications of the original technique are given in detail. A statistical summary of 21 cases is included.

THE RELATIVE VALUE OF SEVERAL DIAGNOSTIC TESTS FOR CHRONIC SIMPLE GLAUCOMA*

SYLVAN BLOOMFIELD, M.D.,† AND LEO KELLERMAN, M.D.
New York

The diagnosis of chronic simple glaucoma is established without difficulty when, in a quiet eye, the intraocular pressure is found to be above the normal range, or when advanced signs of glaucoma are present, such as marked excavation of the nerve head, or typical field changes. In such eyes, the course of the disease has usually advanced sufficiently to reveal its presence by the irreversible changes it inevitably produces if uncontrolled. There are, however, patients who consult the ophthalmologist because of ocular symptoms that suggest the presence of chronic simple glaucoma, but who have normal ocular tensions even on repeated examinations. Such patients may show either no functional or anatomic signs of glaucoma, or insufficient evidence for such a diagnosis to be made. The diagnostic challenge such patients present is important, since the absence of definite evidence of chronic simple glaucoma does not eliminate the possibility of that disease being present in a mild or early stage. At such a time proper diagnosis and treatment are urgently necessary to prevent the insidious development of more advanced ocular damage.

Because of the frequent difficulty in detecting early chronic simple glaucoma, many diagnostic procedures have been devised. Since the purpose of these methods generally is to demonstrate the presence of the disease by producing an abnormal increase in the tension of the affected eye, they are often referred to as provocative tests. Our purpose in this investigation

was to study the diagnostic value of several of the more commonly employed of these procedures, and to compare their efficacy with that of a new test recently devised. The older diagnostic methods investigated were the dark-room test,¹ the caffeine test,² the mydriatic test,³ the water-drinking test,⁴ and the record of the 24-hour ocular tension curve.⁵ The newer procedure studied was the so-called lability test recently described by Bloomfield and Lambert.⁶

The eyes to which these tests were applied had each been previously found to have an intraocular pressure of over 30 mm. Hg (Schiotz), on several occasions. Most of them presented some confirmatory stigmas of glaucoma, such as excavation of the disc and characteristic field changes. When present, such signs were usually early and of mild degree. Gonioscopic examination was not performed on these eyes since our purpose, essentially, was to apply these tests to an average series of eyes with early chronic simple glaucoma, rather than to differentiate the results according to angle depths. At no time had evidence of intraocular inflammation been present in any of these eyes, and the diagnosis of chronic simple glaucoma seemed certain in each case. Eyes that had apparently suffered only acute congestive episodes were not included in this series. None of the eyes studied had undergone any operation, and the tension of each was apparently controlled by the instillation of pilocarpine.

For the purpose of our investigation, the medication of a group of such eyes with known chronic simple glaucoma was discontinued under observation. If the ocular tension rose above normal in any

† Research Fellow in Ophthalmology, The Mount Sinai Hospital.

eye, the administration of miotics was re-instituted and the patient excluded from this study. However, in many eyes the intraocular pressure remained within normal range, that is, below 30 mm. Hg (Schiotz), for 24 hours without medication. These eyes were tested, during such an interval of normal tension, with one or more of the diagnostic procedures under investigation. In this way, each experiment simulated the clinical problem of a patient who presents himself with normal ocular tension, but whose history suggests the possible presence of chronic simple glaucoma. This, of course, is the circumstance under which these tests are usually employed. Since each of the eyes in this study had previously shown definite evidence of the disease, the diagnostic value of each of these tests could be evaluated statistically from the number of positive results that occurred in this series. In other words, an ideal test would be positive in 100 percent of these cases.

In reviewing the literature on these diagnostic procedures, it was frequently found that the difference between the normal and abnormal responses to many of these tests was not clearly defined. For the purpose of this investigation it was, therefore, necessary to derive quantitative limits of normality from certain standard textbooks, when such criteria were not presented in the original descriptions of the tests. This seemed proper since these are the tonometric standards most commonly employed by ophthalmologists in the clinical performance of these procedures. For certain of the tests no definite standards whatever were found, and in such cases it was decided that rises in tension must exceed 6 mm. Hg (Schiotz), to be considered abnormal. It seemed questionable whether lesser elevations could be considered of definite diagnostic significance, in view of the limited accuracy of tonometry.⁷ Throughout this

investigation, ocular tensions were measured with the Schiotz tonometer, and recorded in millimeters of mercury in accordance with the chart accompanying that instrument. All the tonometric results that are numerically expressed in the description of the tests that follow, refer to that scale of measurement.

The dark-room test devised by Seidel¹ is performed by measuring the tension of the eye suspected of glaucoma before and immediately after the patient had been seated in a completely dark room for one hour. The occurrence, during this period, of an appreciable rise in tension is usually considered indicative of the presence of chronic simple glaucoma. According to Duke-Elder⁸ such a rise must be more than 6 mm. Hg (Schiotz), in order to be considered of diagnostic significance. In our experiments, 29 eyes in 22 patients, with a definite history of chronic simple glaucoma but with normal tension at the time of our study, were subjected to this test. In five of these eyes, or 17 percent, a rise in tension of more than 6 mm. occurred, to demonstrate the presence of that disease. In the remaining 24 of these eyes, lesser rises occurred to give misleading normal results. During this test, in six of the eyes in this series, or 21 percent, the tension rose over the level of 30 mm., which is usually considered the upper limit of the normal range of tension.⁹ The effect of the dark-room test on each eye is recorded in Figure 1.

The caffeine test² was performed by having each patient tested drink two large cups of dark black coffee in quick succession. The tension of each eye was measured before the drink was imbibed and thereafter at 15 minute intervals for one hour. According to Duke-Elder,⁸ in glaucomatous eyes a rise in tension should occur that may be 15 to 20 mm. Hg (Schiotz). No actual numerical standard for the normal limit of response to this

test could be found by us in the literature. For the reason previously mentioned it was decided that any rise in tension of more than 6 mm. was abnormal. Eighteen eyes in 13 patients with known chronic simple glaucoma were subjected to this caffeine test. Of these, only one eye, or 6 percent, showed a rise in tension of more than 6 mm. Lesser rises were recorded in six other eyes as shown in Figure 2, which demonstrates the effect of this test on all the eyes in this series. As is indicated, in no eye was the tension elevated above the normal limit of 30 mm. after the ingestion of the caffeine.

The diagnostic value of the mydriatic test³ was studied by the instillation into the eye of one drop of a 1-percent solution of paredrine three times at 10-minute in-

DARK-ROOM TEST

in this investigation since its intense and prolonged action occasionally precipitates acute congestive glaucoma; a condition less likely to be caused by paredrine. Furthermore, Kronfeld, McGarry, and Smith¹⁰ have demonstrated that mydriasis due to homatropine is often not effective in raising the tension of eyes with chronic simple glaucoma of the so-called "wide-angle" variety. Euphthalmine, with which this test had usually been performed previously, was not available because of war-time conditions. According to Duke-Elder,³ Gradle,¹¹ and others, no rise in intraocular pressure should be produced by mydriasis in a normal eye, and a measurable increase should be present in eyes with chronic simple glaucoma. Since no quantitative limit to the normal tension response to mydriasis could be found in the literature, we considered any rise in tension of more than 6 mm. to be an abnormal response to this test. Fifteen eyes with chronic simple glaucoma but normal

The lability test devised by Bloomfield and Lambert⁶ is a method for measuring the ability of the eye to maintain a relatively stable tension in the presence of sudden transient intraocular hyperemia. The procedure they described is, basically, the simultaneous application of the cold pressor test of Hines and Brown,¹⁵ and the jugular compression test described by Schoenberg.¹⁶

Bloomfield and Lambert⁶ demonstrated that neither of these two procedures alone produced diagnostically significant effects on eyes with chronic simple glaucoma. However, the combination of the two in the lability test proved to be more informative.

The lability test is performed by first measuring the tension of each eye to be tested. A blood-pressure cuff is placed loosely about the patient's neck. The patient then places the open hand in a basin of ice water up to the wrist. Simultaneously, the blood-pressure cuff is inflated to a pressure of 50 to 60 mm. Hg, as read on the attached sphygmomanometer scale. At the end of exactly one minute, the ocular tension is again recorded with the hand still in the ice water, and the cervical pressure undiminished. Thereupon, the hand is withdrawn, the pressure cuff removed, and the test is over, unless a repetition is desired for purposes of accuracy. The tension in all cases returns to its original level immediately.

At this hospital, this procedure has been performed on over 300 patients without serious complaint or undue discomfort. Old patients and hypertensive patients have been subjected to it without a single complication. The test is easily and quickly performed and only a few technical points must be remembered. One is that the water must be ice cold; for that purpose chipped ice is usually placed in the water about a quarter of an hour before use. It is also necessary that the bladder in the

pressure cuff be applied anteriorly on the neck so that both jugular veins are compressed simultaneously without protection from surrounding structures. Furthermore, the pressure must be maintained at just below 60 mm. Hg until after the tension is recorded, which should be after precisely one minute. The patient can

breathe quite easily with such pressure about the neck, and, of course, at such levels, arterial circulation is unimpeded. Although some reddening of the face occurs, no real discomfort is experienced by the patient.

In the original description of this lability test,⁶ it was shown that if, in any eye, this procedure produced a rise in ocular tension of more than 9 mm. Hg (Schiötz), the diagnosis of chronic simple glaucoma was strongly suggested. However, if the height or ceiling to which the ocular tension rose exceeded the normal limit of 30 mm. whether or not the actual rise exceeded 9 mm., such a diagnosis was even more conclusively indicated. On the basis of these standards, in only 1 of

77 nonglaucomatous eyes was a distinctly abnormal result recorded by this test; while in almost every eye with chronic simple glaucoma that was tested at that time positive responses were obtained. These diagnostically significant responses resulted from tests applied only to eyes with chronic simple glaucoma. There is

Fig. 6. (Bloomfield and Kellerman). Tension response induced by the lability test when applied to eyes with chronic simple glaucoma.

some evidence to suggest that eyes that have suffered acute congestive glaucoma may not display an abnormal lability of ocular tension by this method when they have recovered from an attack and are in a quiescent phase.¹⁷

To determine further the diagnostic value of the lability test, it was applied in our investigation to a series of 34 eyes in 24 patients with definite histories of chronic simple glaucoma, but with normal tensions at the time of our experiment, exactly as had been done in the study of the other diagnostic procedures. In 31 of these eyes, or 91 percent, rises in tension occurred that were 9 mm. or more. When the height or ceiling to which the tension rose in each eye was employed as a standard of response, as is preferred, it was found again that in 31 of these 34 eyes, or 91 percent it had risen above the normal limit of 30 mm. In the case of the other

three eyes in this group, the ceiling or height of tension reached was exactly 30 mm. which would be considered suggestive but not definitely indicative of the presence of chronic simple glaucoma. All these results are shown in Figure 6 in which the actual rise in tension and the ceiling reached in each eye is indicated. In no performance of the lability test in this series was undue discomfort or any complication noted.

Two or more of these six diagnostic procedures were applied to many of these eyes. This afforded the opportunity to compare directly the diagnostic efficacy of these tests when applied to the same glaucomatous eye with normal tension. In Figures 7 and 8 are shown the rises in tension that occurred when three or more tests were applied at different times to each of 24 eyes. It is apparent that in a large majority of these eyes, the lability and water-drinking tests produced a markedly greater rise in tension than did any of the other diagnostic procedures. This observation indicates that in addition to their greater diagnostic reliability as previously demonstrated, these tests produce an abnormal response in eyes with chronic simple glaucoma that is usually more distinctly appreciable than that of the other tests studied.

COMMENT

In evaluating a diagnostic test, the primary consideration is its reliability in demonstrating the presence of the disease for which it was devised. Secondary considerations affecting the practical value of any test are its simplicity of interpretation and its ease of performance.

A prime necessity for a dependable test is, of course, the establishment of reliable criteria to differentiate normal responses from abnormal ones. It was not the purpose of this study to determine such standards for any of these tests, but rather

to ascertain the reliability of these different procedures, using the standards most often employed in their clinical application. The poor results obtained in certain of these tests, therefore, may be due to the common use of faulty criteria in their

interpretation rather than to the actual unworthiness of the procedures themselves. In any case, however, it is important to be aware of the misleading information that such tests may yield, in their present form.

It may be noted that the results of provocative tests are generally interpreted according to the rise in tension that they produce in any eye. To explore the possibility of applying a single standard to all of them, the actual height or ceiling to which the tension rose in these eyes during each test was noted. Since 30 mm. Hg (Schj  tz) is generally accepted as the upper limit of normal intraocular pressure,⁹ any elevation in tension above this level, no matter how produced, might be considered indicative of glaucoma. This concept of a normal ceiling for variations in a homeostatic system was described by Hines and Br  wn¹⁵ in their elucidation of the cold-pressor test for essential hypertension, and was adopted by Bloomfield and Lambert⁶ as a standard for the lability test. As is shown in the charts for each test studied here, the eyes in which abnormally high rises in tension occurred were usually, although not always, the ones in which intraocular pressure was elevated to abnormal levels; that is, over 30 mm. Hg (Schj  tz). Of even greater interest is the fact that the number of positive results obtained with each of these tests on these glaucomatous eyes was approximately the same whether the standard of abnormality was the span of fluctuation in tension that occurred, or the elevated level of tension or ceiling reached in each case. In other words, the reliability of each of these tests appears to be approximately the same no matter which of these two criteria is employed in its interpretation.

Our investigation has shown that the so-called lability test whose effect is produced by the induction of a transient intraocular hyperemia is the most reliable of the diagnostic procedures studied. It should be pointed out that this result applies only to eyes with chronic simple glaucoma, since no eye was studied that had either secondary glaucoma or recur-

rent episodes of acute congestive glaucoma followed by periods of apparently normal tension. The water-drinking test proved to be almost as trustworthy as the lability test. The 24-hour study of ocular-tension variations proved of decidedly less diagnostic value in these eyes with known chronic simple glaucoma. This suggests either that the 24-hour curve of tension variations is not as reliable an indicator of the disease as is usually supposed, or that the standards usually employed for its evaluation are at fault. The dark-room test proved to be of questionable diagnostic value. The response to the caffeine test and to the mydriasis produced by paredrine indicated that no diagnostic significance could be attached to these two procedures.

Another important consideration in evaluating the diagnostic worth of any clinical procedure is the ease of interpretation of its results. It is obvious that however consistently a test might produce rises in tension in eyes with chronic simple glaucoma, if such increases were often so small as to be attributable to the limited accuracy of tonometry, they might frequently be overlooked and the results of the test incorrectly evaluated. It was for this reason that in studying these procedures an elevation of at least 6 mm. of Hg (Schj  tz) was postulated as necessary for positive diagnostic significance, and that a greater rise was considered even more desirable. In Figures 7 and 8, it is demonstrated that the elevations in tension produced by the lability test, and by the water-drinking test to a lesser degree, are generally significantly greater than those produced by the other procedures considered.

Of lesser importance, but worthy of consideration, is the ease of performance of each of these tests. The lability test requires no unusual apparatus, and is by far the quickest, since it can be performed

in a little over one minute. This speed of performance permits a repetition of the test in a relatively short period, if desired, for purposes of accuracy. The other diagnostic procedures here considered all require much longer periods of time for their performance, as described. The water-drinking test, which is the only one that approaches the lability test in reliability and degree of response evoked, requires that the patient be tested before breakfast, and that tonometric readings be taken for one hour. The inconvenience of such a procedure emphasizes the general superiority of the lability test as a diagnostic method for the early detection of chronic simple glaucoma.

SUMMARY

Six tests commonly employed for the diagnosis of chronic simple glaucoma were

applied to a series of eyes with that disease but with normal tension, at the time of this study, although medication had been interrupted.

The presence of chronic simple glaucoma was demonstrated in these eyes most consistently by the lability test of Bloomfield and Lambert, closely followed in reliability by the water-drinking test.

In decreasing order the diurnal tension curve, the dark-room test, the caffeine test, and the response to mydriasis induced by paredrine, proved much less dependable.

The lability test also produced the most appreciable tension responses in these eyes, and seemed the quickest and most convenient procedure to perform.

LIPIODOL STUDIES OF CHRONIC DACRYOCYSTITIS

SIDNEY A. FOX, M.D.

New York

Functionally the lacrimal drainage system is an elaborate mechanism. Normal tear conduction depends on: (1) lids with their mucous glands that are normal in position and function; (2) atmospheric pressure and humidity for partial evaporation of tears; (3) massage action of the orbicularis; (4) capillarity to draw tears from the lacus lacrimalis into the canaliculi; (5) vacuum-created suction to carry tears into the sac; (6) gravity to draw tears into the inferior nasal meatus, and so forth.

Anatomically, normal tear conduction depends on the integrity of a potential channel of almost microscopic caliber possessing a number of sharp angulations. The anatomy of this system is familiar to all ophthalmologists and requires no elaboration, but it should be recalled here that, although the lacrimal sac and duct are potential cavities, actually they are mere slits whose lumina merge imperceptibly both anatomically and histologically. There is not much difference in the size of the two lumina, so that they comprise one continuous functioning tube—normally. However, this tube is lined with a delicate mucosa which is constantly exposed to infection to which it all too frequently succumbs. The lower end of this tube, the nasal duct, is especially vulnerable and likely to upset the whole delicate drainage mechanism. This has been known for a long time. For while contraction and malposition of the puncta, stricture and obstruction of the canaliculi, descending infections from the conjunctival sac, and many other factors may play a part, by far the most commonly cited cause of chronic dacryocystitis in the adult is an ascending infection from the nose.

Fuchs¹ states: "The immediate cause of

a chronic dacryocystitis is stricture of the nasal duct. . . . The constriction . . . develops, as a rule, in consequence of affections of the nasal cavity." De Schweinitz² says: "In the majority of cases, blennorrhea of the sac is caused by a retention of the secretion on account of stricture or obstruction in the nasal duct, and the participation of the lining of the sac in an inflammation of the nasopharynx." Parsons,³ while not so overwhelming in his indictment, also states that: "Chronic dacryocystitis is commonly attributed to the effects of stricture of the nasal duct. . . . Obstruction to the lower end of the nasal duct may be caused by the pressure of nasal polypi, an hypertrophied inferior nasal turbinate bone, extreme deviation of the septum, and so on." Collins and Mayo⁴ state unequivocally that: "Inflammation of the lacrimal sac (dacryocystitis) is always accompanied by obstruction of the duct. . . . The common causes of lacrimal obstruction. . . . are . . . in adults, —inflammatory affections of the mucous lining spreading from the nose."

In a recent comprehensive review of the whole subject Garfin⁵ comes to the conclusion that: "Dacryocystitis is contingent on stenosis of the nasolacrimal duct, either congenital or acquired, plus a secondary infection. The opinion of the majority of authors cited is that the etiological factor is usually to be found in the nose in the form of an acute or chronic inflammation or in disease of the sinuses. Trauma, physical or surgical, and infectious diseases of the nose may also play a part in the causation of dacryocystitis."

REPORT ON LIPIODOL STUDIES

The X-ray studies shown here are of interest because they present in graphic detail visible testimony of the effect of

Fig. 1 (Fox). a, Early nontraumatic, chronic dacryocystitis before sac dilatation. b, Same case 16 months after dacryocystorhinostomy showing free passage of lipiodol into nose.

chronic inflammation and trauma on the nasolacrimal drainage channels. They were obtained by injecting the sacs in various types of chronic dacryocystitis with lipiodol before the X-ray studies were made. These photographs have been selected from a large series and are typical of the common findings.

TECHNIQUE

The technique of lipiodol injection into the lacrimal sac is simplicity itself. An ampule of lipiodol is placed in warm water for a few minutes. The sac to be injected is thoroughly irrigated and gently massaged to assure its emptiness. The lipiodol is drawn up into a small syringe and injected through a lacrimal needle into the sac in the usual manner of sac irrigation until the lipiodol is seen to flow back into the conjunctival sac. Excess lipiodol is then wiped out of the conjunctival sac and X-ray plates, a-p and lateral, are taken within a half hour of injection.

In order to simplify presentation and discussion the cases have been divided into three groups.

NONSPECIFIC CHRONIC DACRYOCYSTITIS

Figures 1 and 2 are typical cases of the nonspecific type of chronic dacryocystitis

commonly seen by ophthalmologists. The sac in Figure 1a and the smaller sac in Figure 2 are early cases before distention has occurred. Both are good illustrations of an approximately normal sized sac soon after obstruction has occurred. The larger sac in Figure 2, on the other hand, is a six-months-old case in which a mucocele is already present. Figure 2 is interesting because it shows a bilateral case, the mucocele being the result of a persisting chronic inflammation, while the smaller sac has been obstructed for only 21 days. It shows strikingly what a lasting

Fig. 2 (Fox). Bilateral, chronic dacryocystitis. Larger sac has been involved for six months; smaller sac for only three weeks.

Fig. 3 (Fox). a, Traumatic dacryocystitis with huge mucocoele nine months after bullet wound of left orbit with point of exit behind left ear. b, Same in lateral view showing forward bulging and dilatation. c, Same following dacryocystorhinostomy (negative has been reversed). There was no direct trauma to the sac.

inflammation does to the nasal sac.

Note that in all three sacs the obstruction starts at the upper end of the duct and that all three are narrower above near the dome and wider below. This is typical.

TRAUMATIC CHRONIC DACRYOCYSTITIS WITH INTACT SAC

Among recent war casualties, many cases of chronic dacryocystitis were seen which were the result of trauma to the eyes and other tissues surrounding the lacrimal sac and duct. This included trauma to the inner half of the lids, especially the lower punctum, the nose, the ipsilateral sinuses, the jaw, and the lacri-

mal passages themselves; in other words, any type of trauma to the lacrimal passages or the adjacent tissues which would interfere with normal tear conduction and lead to lacrimal stasis and its ensuing syndrome.

Despite the difference in initiating etiology the sacs in Figures 3, 4a, and 5 all show mucocoele formation not unlike that seen in Figure 2 and the reason for this is that the sac always reacts to obstruction in the same way. In such cases the inflammation and infection are usually consequent to stasis and not the causative factor, but the intact sac behaves similarly in both conditions and gives the same ul-

Fig. 4 (Fox). Bilateral, traumatic, chronic dacryocystitis seven months after injury by bullet which entered the left angle of the jaw and came out through the right orbit causing fractures of the facial bones and both orbits. a, Mucocoele of intact sac indistinguishable from that of the non-traumatic type. b, Small sac with absent dome due to direct injury and consequent strictures. timate clinical picture; that is, obstruction of the duct end, dilatation, and final mucocele formation (figs. 2 and 4a).

TRAUMATIC CHRONIC DACRYOCYSTITIS WITH SAC INVOLVEMENT

Where there has been trauma to the sac the X-ray picture is entirely different. Thus, Figures 4b, 6, 7, 8, and 9 show sacs radically different in outline from the others. The most striking differentiating feature is that all these sacs are *smaller* than normal (figs. 1a and 2). Furthermore, they are all misshapen, showing irregular outlines due to strictures in and around the sac and consequent reduction of contents. Figure 4 is an interesting case of bilateral traumatic chronic dacryocystitis, with Figure 4a showing an intact sac indistinguishable from the nonspecific type. The sac in Figure 4b, however, was *directly* involved in the same injury and shows it by reduction of the lumen and a missing dome. In Figure 6, the sac is not only small but is wider above. This is contrary to the usual picture seen in the untraumatized sac. Figure 7 shows a tiny

Fig. 6 (Fox). Traumatic, chronic dacryocystitis seven months after jeep accident in which the patient sustained fractures of the nasal bones and direct trauma to the sac. Note that the sac is small as compared with those shown in Figures 3, 4a, and 5, and that the upper part of the sac is wider than the lower portion. This is contrary to the usual picture in nontraumatic dacryocystitis.

residual functioning sac cavity into which lipiodol was injected with some difficulty. Figure 8 shows a similar sac only slightly larger. The functioning portion of both these sacs is below the canthal ligament, the dome being obliterated. Figure 9, on the other hand, shows only the upper portion of the sac to be functioning and even this is not free of adhesions, as may be seen. All these abnormal manifestations are due to adhesions in and adjacent to the sac. Also, here as in all other cases, the duct is not visible.

DISCUSSION

These X-ray findings seem to corroborate what has been previously known about the cause of chronic dacryocystitis and are compatible with our knowledge of the anatomy and physiology of the nasolacrimal drainage system. The nasolacrimal sac normally holds about 2 cc. of fluid, a capacity which is more than adequate for the transmission of the 0.3 to 0.5 cc. of tears normally secreted per day. Not only that, but the sac is quite elastic

Fig. 5 (Fox). Traumatic, chronic dacryocystitis 9½ months after shell fragment wound involving both antra. Note distention and convolution of intact sac and its relation to lid edges outlined with lipiodol. Patency was maintained for a while as shown by the free passage of lipiodol into the nose. It was finally necessary to resort to surgery.

Fig. 7 (Fox). Traumatic, chronic dacryocystitis with sac involvement four months after shell-fragment injury of nose and antrum. Most of the sac lumen is obliterated with only a small part of the lower portion left patent as seen by relation to lid edges marked out with lipiodol. This was enough to give a purulent dacryocystitis and extirpation of the sac remnant was required preceding plastic surgery.

and, being covered anteriorly and laterally by yielding tissue, is easily distended by internal pressure to hold five times this amount, if necessary. This happens frequently as shown above. On the other hand, the nasal duct which is only about 15 mm. long runs in a bony canal formed by the maxilla, the lacrimal bone, and the lacrimal process of the inferior turbinate. This allows for but little, if any, distention.

Another anatomic fact noted by Wolff⁶ furnishes an additional reason for this being the common site of the obstruction. The sac itself slopes gently outward, while the duct inclines somewhat inward. Hence, at the point of junction there is a slight but definite angulation as well as constriction, and it is here that the obstruction usually occurs. In other words, this is the beginning of the narrow, indistensible portion of the channel and usually the highest point of obstruction. This has been corroborated by Halle⁷ and others. In addition, Schaeffer⁸ states that the lumen of the nasolacrimal duct is frequently irregular and tortuous and not in-

frequently shows outpouchings and diverticula, all predisposing to stasis and consequent stricture. Jacod,⁹ as well as others, has pointed out that the thinness of the wall between the lacrimal passages and an infected ethmoidal sinus makes the former quite vulnerable to such infection. Thus, given an ascending infection from the nose or sinuses with a consequent involvement of the nasolacrimal mucosa, the duct, having no room to distend, will soon become clogged up and strictures will rapidly develop. Even in the early cases shown in Figures 1a and 2, the duct is already closed. The sac, however, will be dilated with mucopurulent secretions from the infected mucosa and retained tears, the walls will become thickened, and the result will be the usual mucocoele of chronic dacryocystitis. This is why probing, unless done very early, is so rarely successful.

When the sac has suffered no trauma, it will always be found to be narrower at the dome and wider below (figs. 1, 2, and 4a). The reason is this: Although the chronically infected sac is closed at both ends, the upper fundus portion is covered by the internal canthal ligament which is

Fig. 8 (Fox). Traumatic, chronic dacryocystitis with sac involvement 14 months after injury to bridge of nose. Note the irregularity of the sac outline and absence of the dome, as compared with Figures 1 and 2.

a tough inelastic fibrous tissue allowing for but little distention. The portion of the sac below the internal canthal ligament, however, is covered only by a few fibers of the orbicularis and this area is the first to distend because there is little resistance here. This is also why most of the abscesses and fistulas of the sac break through at this point. A possible subsidiary cause may be the fact that the upper part of the sac has an outlet

pending only on where the trauma is. It has been shown above that in such cases the sac is always smaller than normal and irregular in outline. In fact, the sac lumen may be so reduced as to be almost absent (fig. 7). Despite this, even these cases develop a chronic dacryocystitis, which has to be reckoned with if surgery of the neighboring tissues is contemplated. For, as long as there is any uninjured mucosa left and as long as the con-

Fig. 9 (Fox). a, Traumatic, chronic dacryocystitis following injury to nose 25 months previously. The small amount of lipiodol retained and the absence of the lower half of the sac are due to strictures. Note the normal relation of the canaliculi to the sac as outlined by the lipiodol. b, Patency of the lacrimal channel following dacryocystorhinostomy.

through the canaliculi into the conjunctival sac, and the pressure at the dome is thus relieved. However, this is probably a negligible factor.

It will also be seen that, in all these cases where the sac is intact, the dilatation is forward and not backward, note especially Figure 3b, because of the unyielding posterior bony wall. Sometimes the sac becomes so dilated as to show convolutions. Figure 5 shows such a case in which partial atresia was relieved for a while by probing. Finally, however, surgery was necessary to relieve the obstruction.

When there has been direct trauma to the sac or the closely adjoining tissues, all types of bizarre pictures are possible, de-

nection through the canaliculi remains patent, pus is formed and finds its way into the conjunctival sac. Even in these cases, if there is not too much bony destruction, dacryocystorhinostomy is sometimes worth trying. Figure 9b shows the successful result following operation on such a sac.

The value of X-ray studies of the lipiodol-filled sac in all cases of chronic dacryocystitis is obvious. It not only helps the ophthalmologist to diagnose the type of case with which he is dealing and to ascertain the point of obstruction, but it also shows him what he will find when surgery is carried out. Even better, it will help him to decide whether or not surgery should be undertaken. (In cases such as

shown in Figure 7, for instance, one would hesitate to undertake a dacryocystorhinostomy.) This is a diagnostic procedure which should be used in all cases of chronic dacryocystitis.

There is no intention here to go into detailed discussion of the therapy of chronic dacryocystitis. Early cases without permanent stricture may respond to irrigation and medication or even probing. In cases of long standing, all these measures will usually be unsuccessful. The X-ray studies presented here show that, unless a sac has sustained trauma, it is usually dilated and needs no probing. The duct runs in such a narrow channel and fibrous tissue is laid down so early that probing is usually a painful, useless procedure.

At various times successful results have been reported with the use of setons, cannulae, and grafts of various sorts. The dacryocystorhinostomy, however, seems to have received the widest acceptance from ophthalmologists and it seems to offer the best prognosis for a cure. This point is stressed because it has been stated¹⁰ that, with complete atony of the sac, tears will not be carried into the nose even if the duct becomes pervious. The lipiodol studies shown here prove that any case of chronic dacryocystitis which has lasted for any length of time develops a dilated and frequently atonic sac. Despite

this rhinostomy is successful in the majority of uncomplicated cases.

CONCLUSIONS

Most authorities agree that the common cause of nonspecific chronic dacryocystitis is an ascending infection from the nose or paranasal sinuses causing obstruction of the lacrimal duct. The X-ray studies reported here tend to confirm this.

The lacrimal sac in these cases becomes dilated and atonic when the infection is persistent. The dilatation is always forward and greater below the internal canthal ligament. The sac may become so dilated as to show convolutions.

The same characteristic X-ray picture is seen in cases of chronic dacryocystitis where the sac has become obstructed due to trauma to neighboring tissues but is itself intact.

When the sac is traumatically involved, it is always smaller than normal and irregular in outline. Here also the duct is always obstructed.

An X-ray study of the lipiodol-injected sac is a valuable diagnostic procedure and is of special importance when surgery is contemplated.

I am indebted to Dr. Jacob Reber for his invaluable assistance in this work.

63 East 75th Street (21).

FACTORS IN THE DIAGNOSIS OF ANISEIKONIA AND PAIRED MADDOX-ROD TESTS*

PAUL W. MILES, M.D.
Hanover, New Hampshire

There are 21 aniseikonia clinics in the United States. In our general population, as many as two-million persons may have complaints correctable by aniseikonic glasses,¹ which would otherwise remain unrelieved. This means that about five per cent of those wearing glasses would be benefited by aniseikonic correction.

It may be years before enough refractionists obtain the instruments and acquire the experience necessary to prescribe successfully for this condition. In the meantime, it is important for the refractionist to recognize which of his patients he should refer for aniseikonic study. Unfortunately, no simple screening device has been available, which will positively rule out aniseikonia. The following pages were written in the hope of promoting interest and understanding of some of the problems of handling aniseikonic patients, and to present what bases there are for diagnosis without the use of the standard instruments.

In lieu of aniseikonic correction, many refractionists today rely on altering the subjective monocular refractive prescription to relieve the complaints of patients with severe phoria, high anisometropia, or high astigmatism. Correction for aniseikonia in such patients, however, gives the higher acuity of full correction, with the comforts of stereopsis and high fusional amplitudes.²

IMPORTANCE OF BINOCULAR REFRACTION

Although the patient is to receive a screening and not a prescription test for aniseikonia, the refraction must be done with the utmost care. The aniseikonic pa-

tient is more critical, has high visual acuity in most cases, and not only notices slight changes in the prescription, but may complain bitterly.

There has been emphasis on "balancing the accommodative state" of the two eyes. This is a confusing phrase, because in all normal situations, the accommodation balances itself. Accommodative impulses wherever their origin are distributed equally so that both eyes accommodate equally and synchronously. It is better to say that the refractive lenses over the two eyes should be balanced so that the object and both retinal images are in conjugate focus at any given distance. This has been done by use of the stigmatoscopy refractive method,^{3,4} which has been in use for the past 20 years. All who have used it find it convenient and accurate. The device was present on the original ophthalmoeikonometers, and all of these instruments are still in use, in spite of subsequent "improved" models on which it was deleted for reasons of economy.

Two other methods of binocular refraction are in use: "Sensitometry," by Luckiesh and Moss, Cleveland;⁵ and the "Leland Polaroid Refractor" by Van Wien, Chicago.⁶ The "sensitometry" method is unusual because it uses, as a criterion of focus, not visual acuity but the brightness contrast threshold. This method is highly interesting and deserves more attention. The Leland polaroid refractor is an ingenious device which permits both eyes to see the test objects dimly with intermittent bright illumination visible only to the eye being tested. Both eyes maintain central, as well as peripheral, fixation and concomitant movement, ensuring binocular vision.

* From the Dartmouth Eye Institute.

In ordinary methods of refraction, errors occur due to poor control of binocular conditions. For instance, one will retinoscope a hyperope, add more and more plus until suddenly all the plus must be removed. This is not ciliary spasm. The patient is fixing a distant target with both eyes. When plus spheres are added to one eye, both eyes relax accommodation until the fixation target is blurred, when the other uncorrected eye takes over. This eye was in focus for infinity, and must accommodate sharply to focus on 20 feet. Since both eyes accommodate equally, the retinoscopist is surprised to find that he has added too much plus, and must start over.

The chief advantage of binocular non-cycloplegic refraction is that the test is done under normal working conditions, avoiding peripheral corneal and lenticular aberrations. The test need not be repeated to make sure the patient will consent to wear the prescribed lens combination. The accommodative level is adapted to convergence at all distances so that at no distance will one eye begin to blur. An eye which is less free to accommodate exactly on the fixation point is slightly blurred, and is inhibited in its fusional movements.⁷ If it happens to be the dominant eye, the patient may be seriously handicapped. In exophoria, a binocular refraction results in a prescription more minus for distance. In esophoria, the result is more plus for near. A nonpresbyopic patient with exophoria will find the full monocular correction blurs his vision for distance, due to excess accommodation from convergence stimulus.

It is important to fix the axes of high oblique astigmatism under binocular conditions, because of the high probability of cyclophoria in such patients. The astigmatic axis determined monocularly may be from 3 to 7 degrees different in each eye from that determined under binocular

conditions when the eyes both rotate from the position of rest to maintain fusion.

H. Culbertson, in 1888,⁸ would adjust the cylinder axes in oblique astigmatism binocularly until the appearance of slanting floors or leaning walls was corrected. G. C. Savage⁹ described methods of changing the axis of astigmatism derived monocularly to an axis which would relieve the strain on weak oblique muscles. Dr. Savage went so far as to prescribe weak oblique cylinders for this purpose in the absence of astigmatism.

This binocular adjustment of cylinder axes may be done with paired Maddox rods. Place a base-down prism over one eye in the phoropter or phorometer. Adjust both Maddox rods at exactly 90 degrees to produce two horizontal lines from one muscle light. If the lines appear horizontal and parallel to the patient, there is no cyclophoria. If not, one can gradually rotate one or both cylinders to make each line horizontal and parallel. In practice, this may require a greater axis change than seems reasonable.

A more conservative method is that suggested by the Leland-Van Wien technique. Blur the vision of one eye to 20/40 with a dark glass. The contours of the large letters and the chart edges will maintain concomitant rotations. Then test the cylinder axis on the unblurred eye in the usual way with the Jackson crossed cylinder on a line lower than is visible to the blurred eye. Check the binocular acuity to make sure the cylinder axes have not been changed too much.

CLINICAL FACTORS SUGGESTING ANISEIKONIA

Aniseikonia may be suspected in all patients not relieved by other means, or in patients with inadequate stereopsis. Aniseikonia is common in those corrected for anisometropia, oblique astigmatism, or high ametropia. Patients with phoria

and intermittent tropia may have aniseikonia. Aniseikonic patients are usually doing work of a type which makes critical demands upon binocular vision. In children and students, aniseikonic glasses are prescribed frequently for fusion or reading difficulties.

The most frequent complaint is headache following reading or near work. Patients may complain that long rides or the movies will produce eye strain, headache, vertigo, or nausea. Some have discovered that closure of one eye for certain tasks will reduce symptoms. Headache may be

the visual field is seen from slightly different points of view, can be appreciated physiologically. Changing the magnification of the image of one eye will change the relative differences between the images in the two eyes, and one would therefore expect a change in subjective localization of all objects in view. This is found to be true of objects whose configuration does not lend itself to monocular depth localization.

This binocular distortion can be demonstrated to one with normal eyes as follows: Place an afocal magnifier before

Fig. 1 (Miles). The space-eikonometer test for aniseikonia.

severe enough to be called migraine, and is commonly of many years' duration. There may be photophobia and asthenopia alone.

The patient with aniseikonia frequently does not know that his binocular space judgments are distorted. To detect such distortion, one must eliminate all monocular clues for depth localization such as known size, parallax, perspective, overlay, object movement, and so forth. This is effected in the space-eikonometer test for aniseikonia (fig. 1). Precision in this test is entirely from stereopsis, wherein the small differences between the retinal images of the two eyes which occur because

one eye consisting of trial-case lenses ($-5.00D.$ cyl. ax. 90° \ominus $+5.00D.$ cyl. ax. 90°) displaced about 1 cm. apart. Observe a person with his arms outstretched laterally, and note that one arm is several inches longer than the other. When his arms are stretched anteriorly, the other arm has become longer. At the same instant, any windows, furniture, or other background detail will appear perfectly normal and symmetrical. Evidently one is using monocular clues on the background at the same time one is using binocular clues on the person's arms. This must be selective suppression of parts of an image.

If a normal person were to wear this

lens combination over one eye for a few days, this distortion would become less evident for most ordinary views, because the conflict between monocular and binocular clues is easily won by the monocular. The patient with aniseikonia, according to theory, is unable to suppress properly, and will therefore develop eye strain. When the nervous mechanism controlling eye movements and accommodation is presented with two different sets of stimuli which differ considerably, the normal oscillation of accommodation and extraocular muscle tone is disturbed. Theoretically, this is a cause of phoria.

I was able to wear a 3-percent, axis 180° , aniseikonic lens over one eye for 4 weeks, then a 4-percent, axis 180° , lens over the other eye for 5 weeks without great discomfort. The initial distortion disappeared in 4 days. On wearing oblique aniseikonic glasses for 4 weeks: R.E., 2-percent, axis 45° ; L.E., 2-percent, axis 135° , I had constant, mild eye strain and more persistent distortion. It took much practice to relearn such a game as badminton, while wearing these lenses. Twice daily tests on the space eikonometer and on the ophthalmo-eikonometer showed no tendency for an adaptive process.¹⁰

Monocular occlusion is valuable in the diagnosis and treatment of aniseikonia.¹¹ Unfortunately in some adult patients, occlusion is annoying, and is often not sufficiently complete, continuous, and prolonged to do any good.

One patient (D. E. S., a woman, aged 47 years) was given an opaque contact lens for one eye, and was comfortable for several months. A small perforation of the enamel admitted an unnoticed beam of light, leading to a difficult-to-explain recurrence of her complaint. When the perforation was finally found and covered, she again became comfortable.

Another patient (W. R., a man, aged 32 years) required less occlusion.

He had never been able to play tennis or baseball because of inability to follow a small moving object. A movie would give him such a headache that he would have to go to bed for 24 hours. He had had six refractions in 10 years without receiving wearable glasses. He found that a pair prescribed for his cousin did help him somewhat. He had moderate oblique bilateral astigmatism, which was corrected on one eye by the cousin's glasses and which, in addition, blurred the other eye to 20/70. He found aniseikonic correction relatively comfortable, and obtained stereopsis.

Aniseikonia is obviously impossible in a person with a totally blind eye, but it occurs in rare instances in those with a central scotoma. Defects in peripheral fusion may cause discomfort, as pointed out by Burian.²⁰ However, since aniseikonia cannot be measured when the visual acuity is poor (20/50 or less), other treatment is indicated.

Patients are frequently seen with high corrected anisometropia and perfect comfort. Certainly, in such patients, it is best to leave well enough alone even if one eye is to suppress and eventually become amblyopic. If they are among those actually aniseikonic, they usually show defective stereopsis when tested on the space eikonometer.

For most occupations, binocular vision is not essential. Other factors being equal, a monocular individual drives a car as safely as a binocular. In fact, in close work, monocular workers are found more efficient and subject to less fatigue than binocular. However, any intelligent, cooperative child under the age of 12 years should be urged to develop acuity, fusion, and stereopsis.

To measure stereopsis, stereoscope cards are quite inadequate. Patients may measure 100 percent and not have enough stereopsis to make judgments on the

space eikonometer, and vice versa. The Howard-Dohlman test and the Verhoeff stereoptor are said not to repeat with precision, because the targets subtend too small a visual angle.¹² Experience on the space-eikonometer shows that stereopsis used to determine the position in space of an X-shaped string cross, movable about its center so that the top and bottom or either side may alternately approach the observer,¹³ must be of higher caliber than that necessary to pass the Howard-Dohlman or Verhoeff tests. Many with good judgment on the latter cannot, at least without practice, detect movements of the string cross.

Aniseikonia will solve many anisometropia problems. Some advise a full prescription to obtain high acuity, and tell the patient he must "get used" to the glasses. Others undercorrect, gaining comfort at the expense of acuity. It is likely that those patients who "get used" to such glasses either suppress or have axial ametropia, in which case there is no aniseikonia. In axial ametropia (that not due to curves of cornea or lens), the retinal-image size remains the same whether the eye is myopic or hyperopic, when the correcting lens is placed at the anterior focal point or 15 mm. from the cornea (Knapp's law). If the ametropia is lenticular or corneal, aniseikonia should be proportional to the anisometropia.

In anisometropia, the ocular image behind the more minus of the two refractive lenses is likely to be smaller, and for proper fusion needs magnification. In most of such patients the measured aniseikonia is about 1.5-percent magnification per diopter of anisometropia, at an ordinary eye-wire distance. However, an important group have aniseikonia measured on the "wrong" eye. For instance, if a patient wears: R.E., +1D. sph.; L.E., +4D. sph., one would expect him to require about 3- to 4-percent mag-

nification of the image of the right eye. In some patients, it might be measured over the left, or perhaps, not found.

It has been said that aniseikonic correction for an anisometropic patient may give him comfort by the simpler means of correcting the prismatic imbalance at the various angles of gaze. To refute this, is the large group of patients successfully treated in which the aniseikonia was prescribed over the "wrong eye," increasing any prismatic imbalance introduced by the anisometropia. The use of slab-off prism to correct prismatic imbalance in the reading position is logical, and does suffice for many patients.

A comparison of 100 patients treated successfully for aniseikonia with 100 patients apparently unable to wear aniseikonic glasses was made recently.¹⁴ Of the 200 patients there were 69 in whom the measured aniseikonia was about 1.5 times the dioptric difference in the two eyes, and was measured over the more myopic of the two eyes. Of these 69, 44 were among the success cases, and 25 were among the failure cases. Of the cases in which agreement of the measured with the estimated aniseikonia was in one meridian only, 29 were among the success cases, and 28 were among the failure cases. Of the cases not in agreement, 27 were among the success cases, and 47 among the failure cases.

This suggests that one is justified in prescribing aniseikonic lenses magnifying the image of the eye corrected for more hyperopia only when the measurement is satisfactory and repeatable with precision, and when temporary size fitovers are reported comfortable.

Aniseikonia may appear in patients due to facial asymmetry. There are many patients with slight unilateral enophthalmos, and so many with one eye higher than the other, that the headrest design for the new space eikonometers has been changed to adapt to such differences. Sup-

pose a 4-diopter bilateral hyperope has 2 mm. difference in eye-wire distance (cornea to eye-wire plane). He might have complaint from the 0.80-percent aniseikonia introduced. Geometrically, there is 0.1 percent of aniseikonia per diopter in the refractive lens per millimeter it is changed in eye-wire distance. Table 1 gives the minification of a number of trial-case minus cylinders in the power meridian at various eye-wire distances. (Such lenses must have plano front surfaces, or the curves will magnify and neutralize the minification at 0.25 diopters and smaller.) If a patient with the correction: R.E., +1D. sph.; L.E., +4D. sph., has measured aniseikonia of 2 percent in the right eye, it could be corrected in three ways. First, decrease the left sphere from a +4D. to +2D. Second, place the right lens at an eye-wire distance of 17 mm.; and the left one at a distance of 7 mm. (see table 1). Third, make the thickness and base curve high on the right lens, and low on the left lens. In simple prescriptions, this can sometimes be done by selecting proper Tillyer series lenses directly from stock, lowering the cost.

Aniseikonia may occur in emmetropic or isometropic eyes. At a naval station in 1942, 280 nearly emmetropic trainees were examined for aniseikonia. One was found to have 1-percent aniseikonia, eight had 0.75 percent, and 32 had 0.50 percent. Five cases with severe complaints relieved by afocal aniseikonic glasses occur in the Dartmouth Institute records.

ASTIGMATISM AND ANISEIKONIA

Astigmatism, being primarily corneal, is not commonly axial, and is therefore not subject to Knapp's law. In other words, astigmatism, if asymmetrical, should produce proportional aniseikonia. The experimental data tends to support this.^{19, 17} There is some variation in ob-

lique aniseikonia attributed to cyclophoria which interferes with the space-eikonometer test.

Oblique aniseikonia, an inevitable result of oblique astigmatism, results functionally in tipping of vertical contours in space. When a vertical line is viewed through a minus cylinder, the line appears to rotate, following the rotation of the cylinder. If cylinders (always minus in this paper) are placed before both eyes and rotated converging the axes down, a vertical line viewed by the right eye will appear to rotate clockwise, and that viewed by the left eye counterclockwise. Although the eyeballs may rotate and the images fuse, from the center of the lines as a reference point, there will be uncrossed disparity above, and crossed disparity below. The result is that the fused line will tip away from the observer at the top and toward him at the bottom. The same effect is true of a wall, of a floor, or a table top. Making the cylinders converge above will reverse the effect.

Aniseikonic meridional lenses placed similarly before both eyes will have an identical effect without producing the blur that cylinders cause. These lenses are usually spoken of in the plus, or magnifying axis. Therefore, the correction of aniseikonia caused by converging-up high cylinders is accomplished by positive meridional magnifiers placed in axes likewise converging up. If the astigmatic axes converge down so should the axes of the correcting magnification.

Oblique aniseikonia is measured in terms of the sum of the arc degrees that each of the axes of these aniseikonic lenses must be converged up or down to correct the distortion of vertical lines in space in the target of the space eikonometer. Axes converging up is called plus, and down is called minus.

When all vertical lines are removed from the target, the X-shaped cross will

not tip in space with oblique cylinders, or with oblique meridional-size lenses. Oblique aniseikonia due to the equivalent of: R.E., $-2D.$ cyl. ax. 45° (or 135°); and L.E., $-2D.$ cyl. ax. 135° (or 45°) or more, is considered likely to require optical correction in most patients.

MADDOX-ROD TEST FOR ANISEIKONIA

There are means available to the refractionist by which, in his own office, he can test for aniseikonia by its effect on space perception. This can be done in 10 minutes on the space eikonometer. The same target could easily be set up by a handy man. Requiring even less equipment, however, is the Maddox-rod test, which has not previously been described.

The set up may consist of several flash-light bulbs with push pins, wire, and transformer, arranged so that the lights can be placed in various positions on a dull-black fiberboard background centered near the eye level of a seated patient, perpendicular to his line of vision. Any set of trial-case minus cylinders which have plano front surfaces would be satisfactory.

Place the Maddox rods as in Figure 2(a) to obtain a binocular image of two vertical streaks from two small "muscle lights." The streaks will appear at unequal distances from the observer, if axis- 90° aniseikonia is present, just as in the space-eikonometer target¹³ (fig. 1). Axis- 180° aniseikonia is estimated as in Figure 2(b) where there are three lights, one in the center of each line drawn. Black-tape masks on each Maddox rod produce the target as shown.

If the upper-half lines are not level, aniseikonia is present, just as in the ophthalmo-eikonometer target.¹⁸ In the more detailed directions to follow, the measurements of target distance and visual angle given may be varied for convenience, but are known to give comparable results

with the standard techniques when a 4-foot board and a 6-foot working distance are used. The target lights should not subtend the same angle as the blind spot and the visual axis. If patients have poor stereopsis or fixation, use absolute darkness and dim target lights. In most cases, a small light behind the patient will not interfere.

Place the refractive prescription in the trial frame or phoropter so that any sphere over the right eye is at the same

tral axes of the lenses, and adjust the corneal alignment to equalize the eye-wire distances.

To measure axis-190° aniseikonia, pin two target lights on the central horizontal line of the board, 14 inches apart, equidistant from the patient's eyes. Then place the Maddox rods in the trial frame so that two parallel, vertical lines are seen by each eye. Take care that the lines are fused. Place a minus cylinder axis 90° lens out in front of the trial frame before one eye,

Fig. 2 (Miles). The Maddox-rod test for aniseikonia. (a) Axis 90°. (b) Axis 180°.

eye-wire distance from any sphere over the left eye. If the trial case carries no 0.00 lenses, simply add 0.12D. to both sides. For instance, in the prescription: R.E., +1D. sph. \ominus -0.50D. cyl. ax. 180°. L.E., 0.00, place in the trial frame: R.E., +1.12D. sph. \ominus -0.62D. cyl. ax. 180°; L.E., +0.12D. sph. \ominus -0.12D. cyl. ax. 180° to balance the amount of glass on both sides. Theoretically the central thickness of all lenses used should be equal, because of the magnification factor due to thickness. The Maddox rods can be placed anywhere in the frame, but the images are larger and more sensitive when they are nearest the eyes. However, when masks are used to test axis-180° aniseikonia, the farther the Maddox rods are from the eyes, the greater the precision: Maddox rods as high as 2½ inches in diameter are made, and would make a large target. Center the pupils on the cen-

tral axes of the lenses, and adjust the corneal alignment to equalize the eye-wire distances. To measure axis-190° aniseikonia, pin two target lights on the central horizontal line of the board, 14 inches apart, equidistant from the patient's eyes. Then place the Maddox rods in the trial frame so that two parallel, vertical lines are seen by each eye. Take care that the lines are fused. Place a minus cylinder axis 90° lens out in front of the trial frame before one eye, and ask the patient which of the two vertical lines seems nearer to the eyes. The line on the same side as the eye over which the cylinder is placed will appear nearer than before. If there is inequality, vary the power of the cylinder used, until a lens is found which will equalize the distances of each vertical line. Place this lens in the front cell. Refer to Table 1 to determine its axis-90° aniseikonia. Test the sensitivity by finding the smallest lens that will displace the lines equally when held alternately before the two eyes. This lens may be a -0.12D. cylinder in one with normal stereopsis.

Some aniseikonic patients arrive at a point where the lines appear equidistant, but will see movement with a given cylinder placed over one eye when there is no movement with the same cylinder placed over the other eye. In the eikonometers, there is no analogous problem,

as sensitivity is tested by enlarging or minifying the image seen by one eye alone. If the right eye happens to be the one involved, the space-eikonometer test now in use simply registers poor axis-90° sensitivity and an unsatisfactory prescription. A. Ames, Jr., explains that there is habitual suppression in the eye which is not sensitive. This is presumably the mechanism by which stereopsis impulses are suppressed in the normal eye, as in the experiment early in this paper where one arm is seen to be shorter than the other. The background part of the image of one eye is suppressed axis 90°.

To test a patient for axis-180° aniseikonia takes more time, and requires "fussy" technique. Three lights are pinned on the vertical central line of the board, about 20 inches apart, with the extra light 2 inches below the lower one. Black tape is placed over the upper inner quadrant of each Maddox rod, when they are placed to produce horizontal lines. The two lower lines are fused below, while the upper one is divided by the masks into halves. The two tips should be completely separated about 2 inches. There is a tendency for the eyes to converge and diverge on this target in a dark room, due to absence of any vertical object for binocular fixation. If the masks are properly placed (they must cover more than one quadrant), the tips of the upper lines can be made to approach and recede by the patient manipulating the interpupillary distance knob, while the test is going on. Do not let the tips touch, or there is no sensitivity at all. Keep the head at the proper elevation. It may help to draw a picture.

One patient tested (R. B., a boy, aged 18 years) had intermittent exotropia of 30 diopters, but was not handicapped by this variability. His sensitivity on the test was ± 0.5 -percent magnification, which is comparable to that shown by him on the space eikonometer.

If the left half line, seen by the left eye, appears higher, place a cylinder axis 180° before it of such power that the two half lines appear level. Then test the sensitivity as before with a small cylinder-held axis 180°. Hyperphoria will interfere with sensitivity, and must be corrected. A prism placed in the system does not have to be balanced on the other eye because no curved surface is involved.

In hyperphoria, there is error in this test due to fixation disparity. Therefore, if it is present, invert the target described above for axis 180°, and place the masks on the lower inner quadrants of the Maddox rods. Repeat the above tests, and take the average. Transpose the power and eye-wire distance of the cylinder required into aniseikonia by use of Table 1. Since the table gives minification, the amount should be transferred to the other eye and called magnification to conform to custom.

An analogous method will test axis-90° aniseikonia in patients who have stereopsis too deficient for the method described above. If the patient has pin-point pupils, there will be little sensitivity with the mask tests until the pupils are dilated. Axis-45° or 135° (oblique) aniseikonia cannot be measured by the Maddox-rod method. A mosaic Maddox rod has been made which by producing two lines at right angles could duplicate the target of the space eikonometer. However, since one would need a trial set of aniseikonic lenses, it would be better to set up a string target.

The fusion pattern in the Maddox-rod, axis-180° test is two lines instead of one in order to improve the accuracy of peripheral fusional movements. In this target, the peripheral retina is used. If the visual angle of the elements is too great, judgment is based on images seen with poor acuity. When the angle is too small, the special effect of aniseikonia on the target elements is too small for precision.

The standard space-eikonometer target subtends 9 arc degrees at 10 feet, and the ophthalmo-eikonometer target subtends 4 arc degrees at 20 feet. The space-eikonometer test for 13 inches gives comparable results to those at 10 feet, but similar tests on the ophthalmo-eikonometer for near show wide variations. The "normal" exophoria for near may account for this finding. It is assumed that aniseikonia does not vary with the distance.

Minus cylinders can be used instead of aniseikonic, afocal trial lenses in the Maddox-rod test, because the targets used consist of parallel lines in the same axis as that of the cylinder used. There is no blurring. It can easily be shown on the space-eikonometer, axis-90° target that the subjective aniseikonia measured for various minus cylinders axis 90° up to 2 diopters before one eye produces a straight line graph which corresponds closely to the actual magnification of each cylinder as shown in Table 1. Above 2 diopters accommodation interferes with the test by blurring the lines.

An aniseikonic, trial-lens set would contribute to accuracy in the Maddox-rod test because the lenses would not have to be placed in the precise eye-wire distance that minus cylinders require. Whereas, a minus cylinder will double in aniseikonic magnification in the range between 9 and 22 mm. eye-wire distance, the aniseikonic trial lens will vary insignificantly.

It is obvious from Table 1 that, in measuring and prescribing aniseikonia, all refractive and measuring lenses in the trial frame during measurement must be placed at known distances from the cornea. Otherwise, magnification differences between the eyes cannot be calculated. This fact has discredited all screening devices attempted in the past.

Patients with anomalous retinal correspondence cannot be tested on aniseikonia instruments, because of the extramacular fixation. Anomalous fixation is preferred

even though normal macular visual acuity is present in the deviating eye. To remove the features of the target objectionable to the cerebral macular fusion centers, all peripheral detail in the visual field must be eliminated. This is not effected in any of the ocular-testing devices in common use. Ordinary retinal images are too complex to fuse in these patients, so the less critical anomalous retinal center is used.¹⁰

A patient (R. B., a boy, aged 10 years) was found to have sometimes normal and sometimes abnormal correspondence on the after-image test. Invariably he showed abnormal correspondence on the synoptophore. In a darkened room free from peripheral fusion contours of any kind he used normal correspondence. On the space eikonometer, he saw the target without apparent suppression or diplopia, but was insensitive to aniseikonic changes. On a similar target produced by Maddox rods in a totally dark room, he was sensitive to changes of ± 1 percent, axis 90°.

OTHER EXPERIMENTS WITH PAIRED MADDOX RODS

Place Maddox rods over each eye as in the test for cyclophoria, with a base-down prism over one eye. Set the lines horizontal and parallel, and remove the trial frame carefully. Hold it so that by moving the head up and down, the observer can exert vertical eye movements while looking at the single target light. On looking up, the patient should see the lines converge on the right (incyclophoria), and on looking down, the opposite. These rotary eye movements are best seen at 20 inches, due to the increased stretch and leverage of the oblique muscles during convergence.

Put the trial frame on the patient, adjust the lines parallel, and demonstrate that minus cylinders with axes converging up will make the parallel lines appear converged on the right. Likewise, making

the axes converge down the lines appear converged left. Most persons can detect this change with -0.25 -diopter cylinders. Now, presuming the prism could be removed from the trial frame without changing the setting, the lines could be fused. Such fusional movement produced by minus cylinders converging up would be incyclovergence, and vice versa.

In testing cyclofusional amplitudes, there is a great difference in results depending on the target used. For instance, in using a printed page, cyclofusional amplitudes are surprisingly high, possibly 15 degrees, when tested at the reading distance. When using two vertical lines produced by two Maddox rods, the rotation of the rods necessary to cause doubling may be as high as 10 degrees, compared to about 4 degrees when the lines are seen horizontally. When the lines are seen vertically, and are rotated equally in opposite directions, each eyeball rotates slowly with its line, keeping the fused lines in the sagittal plane but tipped. Due to the phenomenon of stereopsis in horizontally disparate points on the "X," the crossed disparate points are seen as a more distant part of the line using the center of the "X" as the point of reference. This maintenance of fusion requires cyclofusional ocular movements which are very slow, often one second of time per degree rotation of the lines. If only one Maddox rod is turned, the resulting innervations for cyclofusional movements are distributed equally between the two eyes,²¹ and both will turn through equal arcs as long as fusion holds. In this case, the fused line rotates subjectively on a frontal plane as well as on the sagittal plane, and the measured amplitude is only about two-thirds the amount measured if the Maddox rods are rotated equally.

Suppose the patient observes fused vertical lines produced by two Maddox rods, and adjusts the rods so that the fused line appears vertical in both the sagittal

and frontal planes. Suppose the reading of the Maddox-rod marks on the trial-frame axis scales are not both 90° , but one is 88° and one is 92° . Two conditions might cause such an error: cyclophoria and oblique aniseikonia. Cyclophoria can be partially corrected in patients with astigmatism or meridional aniseikonia by proper lenses.

There is an interesting test for stereopsis using Maddox rods. It is astonishing at first sight, because the cause is not immediately evident. Place two lights on the board 6 inches apart on an oblique line about 45 degrees from the horizontal in either direction. Place the Maddox rods to make a pair of vertical fused lines. Then slight rotary movements of one or both of the rods will make the lines appear to advance and recede alternately from the observer for several inches.

Another test with binocular Maddox rods has some theoretical significance in regard to the horopter, and possibly in regard to phorias and fixation disparity. Place three lights on the central horizontal line equidistant, and observe them from a point equidistant from the lateral two. Place Maddox rods over both eyes, so that three fused vertical lines are in view. Some observers will see the center line in front of the plane of the other two, while others may say it is behind. The latter is "normal," at a 6-foot distance. Rare individuals have a tremendous error, which is not merely poor stereopsis.

The phenomenon could be due to the variations of the normal asymmetry in space value of the elements of the nasal and temporal halves of the retina. Given any three vertical lines on a frontal plane, with monocular vision, a normal person will not be able to place the center line exactly equidistant to the other two lines. Using the right eye, some persons will place the center line slightly nearer the right line, and others will place it consistently nearer the left. The error

is often in opposite directions in the two eyes, but is sometimes the same. If two such figures were drawn, and presented in a stereoscope before the two eyes for fusion, the center line would be off the plane of the outer two because of its disparity.

Phenomena of rivalry between the two retinas are readily and strikingly shown by Maddox-rod targets. Pin several lights on the board in an oblique line. In the trial frame, place the Maddox rods with their axes converging so that the binocular view is a field of oblique lines at right angles. After a few minutes staring at this target, a normal person notices a constantly changing patchy disappearance of parts of the pattern. The more lights, the more active the patchy suppression becomes. Any movement of one Maddox rod will cause the other eye to suppress completely for a moment (as in the major amblyoscope). A prism placed before one eye will likewise cause the other eye to suppress.

CONCLUSION

Present beliefs of the author on factors in the diagnosis of aniseikonia are

outlined in a simple manner in the hope of making it easier for the profession to get a foothold in this advanced field. Any patient may have aniseikonia who is not given comfortable vision and stereopsis by the usual procedures, especially when they have anisometropia, high ametropia, or oblique astigmatism.

Tests for stereoscopic acuity are discussed. Those in common use are said to be inadequate because the target angle subtended is too small and the target consists only of vertical and not oblique lines.

Binocular noncycloplegic methods of refraction receive attention. Patients with high oblique astigmatism should be corrected by cylinders at an axis determined when the eyes are fixed on the same point, with enough peripheral detail present binocularly to prevent rotational incommittance.

A method of measuring aniseikonia with paired Maddox rods is described, and various practical matters discussed. This and other Maddox-rod tests are offered for the purpose of teaching and for practical office use.

DETACHMENT OF THE CHOROID AND THE RETINA

ANATOMIC AND OTHER CONSIDERATIONS IN THE DIFFERENTIAL DIAGNOSIS

GEORGE H. STINE, M.D.

Colorado Springs, Colorado

The differential diagnosis between detachment of the choroid and serous separation of the retina, the presence of an intraocular tumor or retinal cyst having been ruled out, is, according to Duke-Elder,¹ ordinarily not difficult, "the solid appearance of the choroidal detachment, its smooth surface (not wavy or mobile as in retinal detachment), and the appearance of normal retinal vessels with their color unchanged, being sufficiently apparent points of differentiation." Shallow or empty anterior chamber, folds in Descemet's membrane, and hypotony occurring in postoperative cataract and glaucoma cases led O'Brien² to suspect detachment of the choroid. Verhoeff³ goes further, stating that, given the above characteristic ophthalmoscopic findings and Hagen's⁴ sign of exaggerated translucency on transillumination, "the diagnosis is certain" and knowledge of previous wound leakage or obliterated anterior chamber is not essential for the diagnosis.

However, the diagnosis is not always easily made, as witness the case reported by Spaeth and DeLong,⁵ of what ap-

peared at first to be choroidal detachment following shortly after corneoscleral trephination. Six months later with the finding of impaired transillumination after cataract extraction, the case was considered to be one of old, stationary retinal detachment due to an unrecognized neoplasm. Since no tumor cells were present in the xanthochromic, viscous "subretinal" fluid obtained by transscleral diathermy punctures, which resulted in reattachment, the final diagnosis was that of unresolved subchoroidal hemorrhage dating from the trephining operation. The case of Verhoeff and Waite,³ which was proved by microscopic examination to be one of spontaneous detachment of the choroid, had been originally diagnosed as separation of the retina.

The ophthalmoscopic picture may be further confused by the coexistence of choroidal and retinal detachment. However, except in those eyes badly damaged by plastic or suppurative iridocyclitis and severe trauma, this condition appears to be very rare, and choroidal detachment seems to be the primary lesion. A search of the literature reveals only seven cases,

although others may have been observed but unreported.

Duke-Elder¹ states that retinal detachment does not follow postoperative choroidal detachment, but may complicate unexplained or spontaneous cases, while Meller⁶ mentions retinal separation as complicating both delayed postoperative (type 2) and spontaneous (type 3) choroidal detachments. Hudson⁷ in his examination of 574 eyes found 153 cases of choroidal detachment. In only one of these was there coexisting myopic separation of the retina. Simon⁸ observed the combined conditions in a case of cyclic albuminuria. Elschmig's⁹ case was that of a middle-aged man in whom the choroidal detachment was assumed to be primary and the retinal separation to be secondary. Recovery followed aspiration of the subchoroidal fluid.

Purtscher¹⁰ reported a case, due to diffuse episcleritis and serous tenonitis, in which he considered the choroidal detachment and complicating retinal separation to be a collateral edema; and the reattachment occurred after subsidence of the tenonitis. In Ziporkes's¹¹ interesting case, there were undulating folds in the temporal retina and a choroidal detachment in the extreme upper temporal periphery associated with a mixed tumor of the lacrimal gland. Following removal of the tumor, both the folds and the detachment subsided.

Extensive retinal separation following choroidal detachment, which developed after combined intracapsular extraction, has been observed by Kirby¹² in a patient afflicted with osteochondrodystrophy and general maldevelopment, and complete reattachment was obtained by extensive surface and penetrating diathermy and trephine-drainage openings.

In Case 11 of the series of Spaeth and DeLong⁵ choroidal detachment developed after the removal of steel wire from the

vitreous via the anterior route, subsided spontaneously, and was followed three months later by retinal separation in the same area. Full recovery followed operation. The choroidal detachment was considered to be the result of trauma and a surgical procedure, and the retinal separation was probably due to uveitis set up by the original damage to the choroid.

Another case, that reported by Nelson¹³ as total retinal detachment following intracapsular cataract extraction with spontaneous reattachment after an acute attack of glaucoma, is worthy of note. Both the present writer and his associate, Dr. K. H. Chapman, had previously interpreted the detachment as choroidal, not retinal.

CASE REPORT

In view of the rarity of spontaneous reattachment of serous retinal separation and the even greater infrequency of retinal detachment complicating choroidal detachment, it would seem proper and of some interest to record my observations in the case reported by Nelson¹³ and to use it to illustrate some features which may prove helpful in the differential diagnosis.

Mr. H. T. W., aged 79 years, was first seen by me on October 20, 1942, giving the history of gradually failing vision in the left eye for the past 12 years, and in the right eye for two years. He had suffered a blow on the left eye, cutting the globe, some indefinite time ago, but apparently no visual damage resulted. He had seen another oculist the previous July or August and was given some drops for the right eye, which he did not use for very long. The patient was obviously senile, and the family commented that he was hard to handle. An attack of blindness following an abdominal operation in 1925 was not mentioned.

The vision of the right eye was reduced to counting fingers at one meter in

the temporal field; that of the left, to light perception and full projection. The right eye was in a state of well-advanced, chronic, simple glaucoma. The macula appeared finely pigmented and slightly edematous, and many drusenlike spots were grouped around the posterior fundus. A hypermature cataract was present in the left eye. Otherwise the eye appeared normal. Tension was: R.E., 30 mm., Hg (new Schiøtz); and L.E., 18 mm. Hg. Testing of the right visual field revealed an irregular, absolute central scotoma of about 8 degrees in diameter and contraction of the upper nasal field to within 20 degrees of fixation for a 1-degree form on the Ferree-Rand perimeter. The diagnosis was: R.E., advanced, chronic, simple glaucoma and senile macular degeneration or central angiospastic retinopathy; L.E., hypermature senile cataract. Miotics were prescribed for the right eye, and cataract extraction of the left eye with guarded prognosis (because of the possibility of bilateral macular pathologic conditions) was advised. Physical examination showed moderate arteriosclerosis, blood pressure 140/75 mm. Hg, inguinal hernia, moderate benign prostatic hypertrophy, internal hemorrhoids, and an operative scar in the epigastrium.

Intracapsular combined cataract extraction was performed on November 17, 1942, under local, cocaine anesthesia, O'Brien akinesia, and retrobulbar injection of 2-percent novocaine and adrenalin. A Stallard corneo-episcleral suture was used, and the limbal corneal section with the Graefe knife included a narrow conjunctival flap above. The anterior chamber was not irrigated, and, after tying the suture, no further procedures other than binocular bandaging was necessary. Homatropine had been instilled preoperatively. The postoperative course was completely uneventful; the

chamber was fully reformed and the iris pillars were in perfect position at the first dressing on the second postoperative day. The corneal suture was removed on the 10th postoperative day, when the eye appeared quiet, the media clear, and the fundus normal except for some grayish mottling of the macula, seen best with yellow light. The wound looked well healed, although biomicroscopy showed a few folds in Descemet's membrane and slight herniation of the vitreous through the pupil. Tension was: R.E., 23 mm., Hg; L.E., 7 mm. The tension varied only slightly during the remaining five months of my service, the highest tonometric reading being R.E., 26 mm. Hg, and L.E., 12 mm. in mid-December. One month postoperatively vision was: O.S., with a +10D. sph. \ominus +3D. cyl. ax. 2° = 0.9. This temporary glass without reading addition was ordered. In February, 1943, three months after operation, a mild attack of acute iritis developed with reduction of vision to 0.2. The condition completely cleared up under a regime of atropine, conjunctival packs of Pregl's solution, two intravenous injections of typhoid H antigen (10 and 20 million organisms, respectively), sulfadiazine (45 gr. daily for 4 days), and treatment of a rather severe rhinitis which was worse on the left side. The vision improved slightly, but was only 0.3 with a somewhat changed correction on March 19, 1943, when all evidence of active iritis had disappeared. There were the residua of faint pigment deposits on the anterior vitreous face and a thin ring of organized exudate around the pupil margin. Fundus examination showed the media to be clear, and in the macula were seen fine, closely packed white dots and three minute hemorrhages at the end of an inferior macular arteriole. A small pigmented patch was noted in the far upper periphery. Mercury, KI, and vitamin-B

complex were prescribed. One week later the vision had dropped to 0.1, but no central scotoma for 1/1,000 or 2/1,000 white or 5/1,000 and 10/1,000 red and green could be detected. However, blue could not be recognized. The blind spot was normal, and the peripheral field was full. It is believed, however, that had one been able to test the patient with binocular fixation on the stereocampimeter, an absolute central scotoma would have been found. Central retinal angiospasm was considered the most likely cause. According to Peter¹⁴ early loss of blue vision indicates disease of the neuro-epithelium, while red and green changes are noted first in lesions of the conducting paths and centers.

On April 9, 1943, almost five months after operation, the phase of detachment began. However, on that day central vision had improved to 0.6 with a correction of a: +11D. sph. \subset +2D. cyl. ax. 45°. Objectively, the anterior chamber was almost empty, the eye was soft, and in the temporal fundus was seen a dark, smooth-surfaced hemispherical mass elevated almost to, but not obstructing, the visual axis. This was interpreted as a classical picture of choroidal detachment by the author and the consultant, Dr. K. H. Chapman. No leak could be demonstrated in the apparently well-healed operative wound. The patient was hospitalized, and bed rest and binocular bandaging were ordered. Saline cathartics, a general diet of whatever the patient wished (because of his "touchy" digestion), continuation of thiamin chloride, and instillations of atropine in the left eye and miotics in the right, constituted the rest of the treatment. Daily fundus examinations showed no change until the fourth day, when the temporal detachment had increased so that it now covered the visual axis, and a similar dark, globular, but less extensive and less elevated

mass was seen in the inferior periphery, with a deep valley between it and the temporal one. No retinal hole nor any sign of serous retinal detachment was found; and the retina did not appear translucent to retro- or para-illumination with the ophthalmoscope. This method of lighting up the surrounding separated retina by throwing the narrow, bright ophthalmoscopic beam slightly off the area under study, a method described by Reese¹⁵ to demonstrate cystic spaces in the macular retina, has been found very useful in differentiating serous and solid separation of the retina.

After 10 days of hospitalization, during which time the patient's coöperation was practically nil (he even made a clandestine trip out of the hospital), the family was consulted and the joint decision to dismiss him to his home was made. He did not return to our care after that.

The further course of the condition has been reported by Nelson,¹³ whom the patient consulted two months later. At that time, the detachment was found to have extended into the nasal fundus, mild iritis had recurred, and a gray film had appeared on the upper quadrant of the posterior corneal surface and in the coloboma, which was considered to be an ingrowth of epithelium. The visual field was lost nasally, this defect being almost exactly the inverse of the detachment in the temporal fundus as we first observed it. The fundus picture continued unchanged until spontaneous reattachment occurred sometime between August 25, and October 1, 1943, that is 4½ to 5½ months after onset. An acute attack of glaucoma had supervened and subsided in July. Full recovery of central and peripheral vision eventually resulted.

This case has many interesting features:—the persistent, postoperative hypotony, inexplicable except on the as-

sumption of microscopic, but clinically undemonstrated, wound leakage or disturbed intraocular vascular balance, as evidenced by chronic simple glaucoma in the right eye, central angiospastic retinopathy in both eyes, acute glaucoma in the left eye, and generalized arteriosclerosis; the delayed onset of the detachment; its extent and size; the supervention of acute glaucoma; and the spontaneous reattachment and recovery of vision approximately five months after onset of the detachment and, even more interestingly, two or more months after subsidence of the acute glaucomatous attack.

The causation of postoperative hypotony and its role in the development of choroidal detachment, the variability of time of onset and duration, the complications, and the prognosis have been thoroughly discussed by the several authors cited above. The matter of size and location has also been considered, first, by Fuchs¹⁶ who stated that choroidal detachments are limited by the vortex veins above and below in the region of the equator so that they occur most often in the nasal and temporal quadrants.

Duke-Elder¹ says that the usual sites are the inferior, inferonasal and inferotemporal quadrants, and occurrence in the upper quadrant is rare; and the detachment may be large enough to occupy half of the fundus and reach back to the disc, and may occasionally extend around most or all of the globe.

Samuels,¹⁷ in differentiating hemorrhagic and serous choroidal detachment, states that both blood and serum are found in greater accumulation in the region of the ciliary body, but, in extending posteriorly, blood may dissect the choroid from the sclera as far back as the optic nerve, while serum is usually confined to the normal narrower limits of the perichoroidal space.

O'Brien,² in his large series of postoperative cases, found that detachments appear first in the periphery and sometimes encircle it, are most often more extensive nasally and temporally than inferiorly, are sometimes flat but more usually elevated into one or more domes, but in no case do they reach backward to the macula or the nerve head. However, in one of his cases the choroidal detachment was massive enough to appear to fill the vitreous chamber. In our patient the temporal detachment was extensive enough to obscure the visual axis and a view of the macula, although it did not reach to the nerve head. Nelson¹³ was of the opinion that a choroidal detachment of the extent seen in this case would be impossible without tearing the vortex veins so that devastating subchoroidal hemorrhage would result.

These various observations are in general, but only general, agreement, and they pose an intriguing anatomic problem. Specifically, how extensive and where can choroidal detachments be without damaging the vortex veins and their ampullae? The solution of the problem may be found by the application of the fundamental principles of physiologic optics and descriptive geometry,¹⁸ a method which I have used in my investigations in intraocular localization.¹⁹ By this method it can be shown to what extent the vortex ampullae limit the height and size of choroidal detachments in the different quadrants and zones of the eye, and an additional factor, that of location, may be brought out to aid in the differential diagnosis between choroidal detachment and serous separation of the retina.

The first step in the solution is the construction by orthographic projection on cross section paper, scale 10 to 1, of frontal, top (horizontal meridional), and profile (vertical meridional) views of a spheric anatomic eye whose dimensions

are the average measurements of normal eyes found in the literature,¹⁹ and the schematic eye of A. Cowan.²⁰ Next are plotted the positions of the vortex veins and ampullae, using the external topographic data of T. Cowan²¹ and the retinal coördinates for intraocular localization.¹⁹ The average distances of the respective vorticoses veins behind the limbus and their meridians of longitude measured with a protractor on Cowan's projection (fig. 1), are as follows:

mm. being attained by the superior temporal vein only. To assure ample clearance of the ampullae by the detachments the maximal diameter (0.5-2 mm.) of the ampullae has been used. Figures 2 and 3 show the average positions of the vortex veins, their ampullae, and other normal ocular structures orthographically in frontal, top, and right-side views of the right eye.

In orthographic projection, unlike perspective or pictorial presentation, the

TABLE I
AVERAGE POSITION OF THE VORTICOSE VEINS

Exits of Vortex Veins				
	S.N.	S.T.	I.N.	I.T.
Distance from limbus (LScS)	19.3 mm.	20.2 mm.	18.0 mm.	17.4 mm.
Corresponding perimetric sighting angle ($\angle Ro$)	38.8°	36.2°	43.8°	46.0°
Meridian, measured from vertical (90°) meridian	39.0°	20.0°	38.0°	9.0°
Vortex Ampullae				
	S.N.	S.T.	I.N.	I.T.
Distance from limbus (LScS)	16.3 mm.	17.2 mm.	15.0 mm.	14.4 mm.
Corresponding perimetric sighting angle ($\angle Ro$)	49.7°	46.7°	54.5°	57.7°
Meridian, measured from vertical (90°) meridian	39.0°	30.0°	36.0°	17.0°

The oblique intrascleral course of the vortex veins is 3 to 4 mm. in length. In Table 1, the ampullae have been placed at the average distance of 3.0 mm., anterior to the exits of the veins along the meridians of the exits of the veins, which results in an intrascleral length of vein to ampulla of somewhat more than 3 mm. but less than 4 mm., owing to the oblique course of the vein on a great circle to the meridian of the ampulla. This is in accord with the data given by Salzmann,²² who gives the usual length of the emissaria as 3 mm., a greater length of 4.6

lines of sight are assumed to be parallel to one another as if the observer were at an infinite distance from the object; and if the direction of sight is perpendicular to the face of the object, the orthographic view shows the true shape and size of that face. A choroidal detachment protruding into the vitreous chamber may be considered to be a portion of a sphere of the same radius of curvature as the normal (undetached) choroidal sphere, and the geometric problem is, therefore, that of the intersection of two spheres which may be solved by the method of cutting

planes. The axis or central meridional plane of each of the detachments was located equidistantly between the meridians of the ampullae, and, inasmuch as these axial meridians do not coincide exactly with the horizontal or vertical meridians, the top (fig. 2) and right-side (fig. 3) views are composite showing the vortex veins and their ampullae in their true positions while the detachments are shown as they would appear in auxiliary oblique views perpendicular to the axial meridional planes (Ad). The plane of intersection of the two spheres is a straight line (a-a', c-c', and so forth), when viewed perpendicularly to the meridional plane, and it will be noted that these lines of intersection, where the edges or borders of the detachments meet the normal surface, have been placed so that the vorticose ampullae have been amply cleared. One may visualize these relations more easily if the frontal views be revolved about the anterior-posterior optic axis (AP) so that the detachment axes (Ad) be made to coincide with the vertical (90°) meridian in the case of superior and inferior detachments (fig. 3), and with the horizontal (180°) meridian in the case of temporal and nasal detachments (fig. 2). In this way the cross-section lines of the graph paper could be used for both views and the work reduced to two drawings. A simple model such as a hollow rubber ball indented to any desired degree up to the maximum, and viewed from different angles, will help to demonstrate these relations.

The line of intersection having been determined (for example, anterior to the ora serrata, c', to the posterior fundus, c, in the temporal quadrant), it was easy to draw the frontal view by the method of cutting planes. The constructions show conclusively that a choroidal detachment in the temporal quadrant (fig. 2), assuming that its anterior border be in the re-

gion of the ora, d', or in the ciliary body, c', may be so extensive as to cover the visual axis and obscure the ophthalmoscopic view of the macula and the posterior pole, whether the determining rays pass through the posterior nodal point (N), or the pupil of exit (Px), without damage to the vortex ampullae. Similarly, a nasal detachment may appear to reach

Fig. 1 (Stine). Projection of the posterior half of the globe measured on the sclera; A, optic nerve; B, macula; C, posterior pole; D, long posterior ciliary arteries; E, short posterior ciliary arteries; F, vortex vein with ampulla and tributaries. (Cowan.)

almost to the nasal margin of the optic disc. Superior and inferior detachments (fig. 3) must be smaller if their anterior borders are in the region of, or anterior to the ora serrata, but they can extend back to the nerve head or posterior limits of the suprachoroida, if their anterior borders are situated posterior to the equator. If the detachment involves the entire expanse, a transverse fold or valley will be seen in it just behind the equator. Nevertheless, peripheral detachments in these quadrants will appear somewhat larger in the ophthalmoscopic panorama than in the orthographic view,

as they may be seen to extend back of the equator to within 45 degrees of fixation (or the posterior pole) with a meridional or transverse spread of 45 degrees or more. In any case, serous choroidal detachments are limited to the quadrants

on the shape of the globe, and rigidity or elasticity of the choroid and retina, and the effect of gravity on the subchoroidal fluid.

The surface area of the detachment, however, must obviously equal the sur-

Fig. 2 (Stine). CHOROIDAL DETACHMENT. Frontal and top (equatorial and horizontal meridional) sections of schematic and average anatomic right eye, showing maximal possible extent of choroidal detachments in the temporal and nasal quadrants, scale 5:1. A, apex of cornea; P, posterior pole of globe and optic axis; M, macula; ON, optic nerve; L, limbus; Re, normal retinal or choroidal surface; Eq, equator; OS, ora serrata; STVV, ST, superior temporal vortex vein; Am, ampulla; SN, SNVV, ITVV, IT, INVV, IN, superior nasal, inferior temporal, inferior nasal veins and ampullae; Ch', detached choroid; Ad, meridional axis of detachment; C, center of retinal or choroidal bulbar sphere; C', C'', C''', and so forth, centers of detachment spheres; a-a', c-c', planes of intersection of the two spheres (detached surface meets normal surface); ⊗, position of center of ampulla in auxiliary views to determine ample clearance of ampullae; 1, 2, 3, and so forth, latitude circles of 10°, 20°, 30° on normal retinal surface (∠Ro); 0, 90, 180, meridians of longitude radiating from anterior and posterior poles; 30m, 39m, and so forth, meridians of ampullae referred to vertical meridian; b-b', d-d', other possible positions of choroidal detachment; N-M, Px-P, determining visual rays, or ophthalmoscopic lines of sight in vitreous. (Note: Latitude circles anterior to equator, on or under surface

of detachments are not shown. Outer scleral wall, ciliary body, and so forth are not shown.)

between the ampullae, or to the region anterior to them, where they may encircle the fundus; and if they are adjacent (for example, temporal and inferior), there will be a deep valley between them extending down to the normal retinal surface in the region of the ampulla.

Detachments need not be sections of a perfect sphere; their shape will depend

face area of the bed from which it is elevated. The true size and shape of detachments, choroidal or retinal, may be determined by plotting orthographically the data obtained by perimetric sighting of the edges along different meridians as pointed out previously,¹⁸ a method which I hope to describe more fully in a later paper.

NOTES, CASES, INSTRUMENTS

RELIEF OF EPISCLERITIS BY HISTAMINE DIPHOSPHATE

EDWIN M. SHEPHERD, M.D.
Charleston, West Virginia

Thinking in terms of counter irritation as a means of finding relief for the pain of episcleritis, my father and I tried histamine diphosphate instilled directly into the eye. I had previously used the drug experimentally in the eye while resident on the eye service at Bellevue Hospital, New York. The immediate relief obtained was far beyond our anticipated results. Looking back, we now believe that the relief afforded is occasioned by the lateral release of pressure on pain fibers exerted by the sharply localized episcleric node. The fairly rapid subsidence of the episcleritis after treatment with histamine may be due to the increased availability of blood produced by the generalized conjunctival flush.

The pain of episcleritis can be relieved for a period of 4 to 24 hours by the instillation of histamine diphosphate (1:1,000) in the conjunctival sac of the involved eye. The relief occurs in from 12 to 45 seconds. The episcleric node loses its tenderness and may be freely palpated. The cornea does not lose any of its sensibility as tested with cotton wool. The duration of relief has varied from 4 to as much as 36 hours. When the pain returns, it is usually mild and can be abolished again in a few seconds by the re-instillation of histamine.

This treatment has been used by my father and me since 1941. In each instance the episcleritis has subsided completely in about three days. We are unable to judge whether or not a recalcitrant episcleritis will yield to this treatment because all cases treated to date have cleared. The number of cases treated (5) is too small to

speak in terms of unqualified success. At least the drug is not harmful to the eye, if properly controlled, and its use will tide the patient over a very painful episode while search is being made for the cause of the episcleritis.

Side reactions thus far encountered in the ocular use of histamine diphosphate (1:1,000) are as follows.

In one case the chemosis was enough to show in the palpebral fissure when the lids were closed. A patch and bland ointment brought a normal conjunctiva in 24 hours. Strong miosis can be produced by repeated instillations even in the presence of atropine mydriasis. In the cases tested there was no undue chemosis. In one case with posterior synechiae from an old iritis which had flared mildly, some of the more medial synechiae ruptured, but the iritis quieted nicely.

Skin sensitivity with typical histamine headache later relieved by desensitization in one case showed no unusual conjunctival chemosis. The conjunctival flush produced could be abolished in a few seconds by a drop of ephedrine sulphate (5 percent). Since thinking of ephedrine as a means of opposing the vascular blush of histamine, we have had no case with sufficient chemosis to test it.

CASE REPORTS

Case 1. A white woman, 45 years of age, reported at the office with her left eye painful for the past 12 hours. Examination showed an episcleric node in the lower temporal quadrant of the eye, exquisitely tender to palpation. The remainder of the examination contributed no pertinent information. Two drops of histamine diphosphate (1:1,000) were instilled. The conjunctiva began to flush in about 12 seconds. There was a stinging sensation and the conjunctiva became

markedly flushed in about 50 seconds. The conjunctiva was slightly chemotic, the pain was entirely gone, and the node could be freely palpated without pain. The eye remained quiet for 18 hours, when it began to pain slightly. The patient returned at the end of 24 hours with moderate pain and histamine was instilled again. The same cycle of stinging and chemosis was repeated with relief of pain. The patient reported that following the first instillation the eye remained red for almost 4 hours and then gradually over another 5 or 6 hours became normal except for the episcleric node which remained congested. At the second visit the node appeared less prominent than the first day and was definitely less tender than before. After the second instillation, the eye became perfectly quiet and the patient failed to report for the general physical survey indicated.

Case 2. A white man, aged 64 years, reported to the office with his right eye painful for two days. Examination showed an episcleric node in the upper temporal quadrant, tender to palpation. Two drops of histamine produced a flush in about 12 seconds and relief in 40 seconds. The chemosis was very slight. Pain returned in about 24 hours, but was so mild that the patient delayed returning until the following day. Histamine again brought relief. A thorough medical examination failed to reveal any source of infection. This attack subsided after the third instillation of histamine. This patient reported back two months later with another episcleric node in the same eye and again in the temporal side. Histamine was used for two days with complete relief.

Case 3. A white man, 25 years of age, an infantryman in the U.S. Army, reported to the hospital with chronic tonsillitis and history of repeated sore throat. Two days after tonsillectomy the right

eye developed an episcleric node on the lower temporal quadrant. Histamine instilled in the eye gave relief for almost six hours. A second dose kept the patient comfortable until the next day. Treatments on each of the two days following gave complete relief. It was felt that the infected tonsils were the source of his trouble in view of his otherwise negative physical examination.

Case 4. A white, 22-year-old infantryman, was wounded in action by mortar fire. One small fragment was imbedded in the episclera of the left eye, temporally, and on admission to our hospital was the center of a tender, red, raised area. The node was plainly visible in depth and contained no pus. The tenderness was characteristically that of an episcleritis. Histamine was instilled with relief in about 45 seconds. Treatment was repeated in about 8 hours. The eye was never, during this time, completely free of pain or tenderness, but so marked was the relief that the use of histamine was continued. This dose was repeated three times the following day and once on the third day. The eye was quiet on the fourth day and the small fragment was removed.

Case 5. A 28-year-old white man reported to my office with a painful left eye of two days' duration. There was a typical episcleric node in the lower temporal quadrant. This was very tender on palpation. Histamine, 4 drops, was instilled. There was relief in 45 seconds which lasted about seven hours. The eye became painful again but not markedly so. Another instillation kept the patient comfortable through the night. The eye was only slightly tender and painful the next morning. Histamine administered once on the second day kept the eye comfortable for 24 hours, and a final dose was then sufficient. This man was referred to an internist for a complete physical check up.

CONCLUSIONS

Histamine diphosphate (1:1,000 solution), when instilled in an eye suffering from episcleritis, will afford immediate and prolonged relief of symptoms without the dangers of local anesthesia. In the cases so far studied it has also led to complete relief from the immediate attack. These are not enough cases to justify calling this treatment an infallible cure. The side reactions noted, miosis and chemosis, indicate the need of sensible caution in using the drug. No strong contraindications have yet been encountered in the local use of histamine diphosphate (1:1,000) in the eye.

A CORNEOSCLERAL SUTURE*

E. W. DYAR, M.D.
Indianapolis, Indiana

Techniques of securing accurate apposition of the limbal incision by sutures, following cataract extraction, have been many and varied. Ellett's monograph† presented this subject most completely. Subsequent articles have corroborated and amplified his thesis.

One feature of the complications attendant on the removal of the crystalline lens is prolapse of the vitreous. If this hazard could be banished, or minimized, the incidence of successful results would be materially increased. It follows that a measure which effects such an end, has merit. The following plan of corneoscleral suturing has proved worthy in many cases.

An apron conjunctival flap is prepared by baring the corneoscleral junction for the upper one third of its circumference.

*From the Department of Ophthalmology, Indiana University School of Medicine.

† Ellett, E. C. *Archives of Ophthalmology*. March, 1937.

A double-armed silk suture is placed in clear cornea at the 10:30- and again at the 1:30-o'clock positions. Corresponding bites are taken in the sclera, with each of the needles approximately 1 mm. behind the limbus. The edge of the conjunctiva is lifted, and the needles are passed from its

Fig. 1 (Dyar). A, the suture is looped laterally and nasally at the limbus; B, the corneal wound can be brought into apposition by a 4-point support; C, lips of the wound can be separated as desired by releasing traction above; D, the corneal suture is tied above, using a minimum of tension.

under to outer surface, 5 to 8 mm. from the free border. The suture is looped laterally and nasally at the limbus as shown in Figure 1-A, and the section is made by whatever method is desired. The remainder of the operation, up to the actual delivery of the lens, can be accomplished without interference from the sutures.

At the time when the lens presents in the wound, the ends of the suture, which are lying on the brow, are picked up by the assistant and gentle traction commenced. Any amount of aperture of the wound can thus be controlled, depending upon the wishes of the surgeon or the expediency of the moment. It is worthy of

note that, as the last portion of the lens is delivered, the corneal wound can be brought into apposition by a 4-point support (fig. 1-B). The lips of the wound can then be separated as desired for irrigation or repositing of the iris, by releasing traction above (fig. 1-C).

The apron flap is brought into place by fine catgut sutures, and the corneal suture is tied above, using a minimum of tension (fig. 1-D). It has been found that the elasticity of the conjunctiva aids in keeping the suture taut, until a measure of healing of the incision has taken place.

Because of the normally high surface tension of the vitreous, it is fair to assume that a large prolapse of that body cannot easily take place through an opening which has been reduced to a slit or closed. In eyes in which fluidity of the vitreous is anticipated, or known to exist, command of the width of the wound aperture is of significant value.

Sutures placed before the section is made do have the disadvantage of not effecting perfect apposition of the lips of the incision, with the exception of the McLean. It has been found, however, that a second suture can be placed at the 12-o'clock position. For this suture, the McLean principle, the Verhoeff tract, or other techniques, which insure more perfect apposition and aid in reducing postoperative astigmatism, can be employed. A bridle suture has been used in selected cases.

Removal of sutures entails little or no danger, in so far as a reopening of the anterior chamber is concerned. It has been our routine not to attempt removal for at least 10 days. As long as three weeks have elapsed before removal in numerous cases, without excessive reaction. Following anesthesia by several instillations of ½-percent pontocaine, that portion of the suture lying exposed between the two corneal bites is gently teased free with a fine foreign-body spud and is severed

with scissors. The upper cul-de-sac is then exposed with a lid hook. The silk is grasped at the knot with curved dressing forceps and withdrawn through the conjunctiva from above.

TEAR SAC PROBED THROUGH CANALICULUS OF EVERTED UPPER LID

ELIAS SELINGER, M.D.

Chicago

Passing a lacrimal probe through the upper canaliculus has certain advantages. Once the probe has been successfully introduced through the upper canaliculus, it is easier to pass it into the nasolacrimal duct, since the upper canaliculus forms a more obtuse angle with the tear sac than the lower one, which is practically at a right angle to the sac. When the tip of the probe is passed through the lower canaliculus, it not infrequently assumes a faulty position in the sac as the shaft of the instrument is brought into a vertical position. In infants and small children, the tissues of the canaliculus are so delicate that false passages and strictures of the canaliculus may result from the trauma incident to faulty technique in passing the probe. Such an occurrence is particularly unfortunate in the lower canaliculus. Since the lower canaliculi play the major part in tear conduction, strictures here result in permanent epiphora. A stricture of the upper canaliculus usually does not lead to interference with the conduction of tears into the lacrimal sac.

One reason for the comparatively infrequent use of the upper canaliculus for passage of the lacrimal probe is the awkward approach due to the position of the punctum and the canaliculus. This makes it necessary to work from below upward.

This difficulty can be easily overcome if the upper lid is everted and held in that position while the punctum and canaliculus are being dilated and while the lacrimal probe is being passed (figs. 1 and 2). Frequently, one can permit the lateral two thirds of the upper lid to fall back into its natural position during the manip-

Fig. 1 (Selinger). Upper punctum being dilated while lid is everted.

Fig. 2 (Selinger). Bowman probe in canaliculus of everted upper lid.

ulation, while keeping the medial one third everted. I have seen no reference in the literature to this technique of probing through the upper canaliculus. I have been using it on adults, as well as on children and infants, for the past three years.

104 South Michigan Avenue (3).

A FOCUSING FLASHLIGHT

I. HERBERT KATZ, M.D.
Syracuse, New York

This focusing light consists of an ordinary large flashlight, a +13.00D. lens, and a holder for the lens (fig. 1).

As illustrated, the flashlight is an army

Figs. 1, 2, and 3 (Katz). A focusing flashlight with the parts separated and assembled.

type (TL 122-B), with a focusing bulb and a plano glass for protection. The bulb focuses at one foot or more and is labeled Tungsol, PR6, 2.5 volts.

The lens, for sale by optical supply houses, is 40 mm. in diameter and is encased in a black plastic rim, the outside diameter of which is 47 mm. The holder is made of acrylic of a size to hold the lens snugly on the flashlight and with a small incurved rim to prevent the lens from falling out (fig. 2). This is the only part of the apparatus that has to be made to order. The one illustrated was made by the dental department of an army hospital.

This illuminating system gives a brilliant 5-mm. spot and focuses at 65 mm., almost regardless of type of bulb. Incidentally, there is considerable variation in the brightness of different bulbs with the same batteries.

The advantages of this light in the study of the anterior segment are its brilliant spot focus, portability, long battery life, and freedom from adjustments, entangling wires, and so forth. It will be found particularly useful in clinics, at the bedside, and where large numbers of patients are to be examined. In the army, it was also useful and satisfactory for intraocular surgery.

DR. BENJAMIN FRIEDMAN, *presiding*

PROVOCATIVE TESTS IN GLAUCOMA

DR. SYLVAN BLOOMFIELD discussed this subject during the instructional hour, see this JOURNAL, page 869.

NEW TEST FOR DARK ADAPTATION

DR. HOWARD AGATSTON stated that testing of the light sense is an important aid in diagnosis, but it has always been a laboratory rather than a clinical procedure. The test combines two techniques, namely bleaching of the retina and perimetry in dim illumination. It measures the course of dark adaptation of the central 60 degrees of retina after preexposure to bright light.

A preliminary visual field is taken on a tangent screen, equipped with a central, red fixation light. A 2-mm. white test object is used at one meter and the extent of the field along the 45-degree, 135-degree, 225-degree, and 315-degree meridians is recorded. The eye is then exposed to the light of an X-ray shadow box for five minutes, and the visual field in dim illumination is plotted at one-minute intervals along any one or more of the meridians mentioned. The only source of illumination is a 15-watt incandescent bulb in a reflector. Its distance from the tangent screen and the angle of the beam (indirect lighting) are adjusted until a normal dark-adapted eye has a 22-degree to 30-degree field with a 2-mm. test object at one meter. This lighting is less than one foot-candle and, therefore, the

eye is used as the photometer. He discussed standardization, normal curves, and interpretation of the curves.

Discussion. Dr. J. Mandelbaum said that the intensity of the light reflected from Dr. Agatston's test objects has not been standardized quantitatively. Judging from his description, the intensity is probably about 0.1 millilambert. At this intensity level, both the cone and the rod cells function normally. He believes that Dr. Agatston's test records the recovery of rod function as well as cone function, after exposure to bright light. It has been demonstrated by Hecht and others that dark adaptation of the cone cells proceeds much more rapidly than it does for the rod cells. The initial latent period before the test object appears at the fixation point for the normal eye represents the time required for the foveal cones to adapt to the level where the approximately 0.1-millilambert stimulus becomes visible. Only after rod adaptation is well under way does the stimulus become evident further peripherally, such as at 20 degrees.

Diminished cone function should be characterized by an increase in the initial latent period. Diminished rod function would be indicated by a recovery curve, whose slope is reduced, so that peripheral recovery takes a disproportionately long time. In order, however, to procure really precise evidence concerning the cone and rod function, more complex apparatus is required. The light-sense test, which would best suit the purposes of clinical ophthalmology, is that devised by Louise L. Sloan. It consists of a light source mounted in a box, that can be attached to the arm of a perimeter and can, therefore, be used to test any

desired retinal area. In front of the light is suspended a photometric wedge and neutral filters to cut down the light intensity. However, until instruments of this kind become available and are put in general use, tests such as devised by Dr. Agatston will be very useful.

Dr. I. Givner asked whether this method would not be of much use in diagnosing an early detachment of the retina which could not otherwise be seen.

Dr. Agatston (in closing) said that the Sloan perimeter with the illuminated test object has in the past been used to measure the light threshold of various points of the retina. The light and/or form stimulus is reduced from minute to minute. In the visual field recovery test, during the period of adaptation, the stimulus remains fixed. However, Sloan's apparatus, if available, could easily be used to make the test. In reply to Dr. Givner's question, Dr. Agatston stated that in retinal detachment a visual-field defect is usually exaggerated in dim illumination. The rate of dark adaptation of the retina near the area of the detachment would undoubtedly be prolonged. This test uncovers the area of depressed retinal function not disclosed by ophthalmoscopy or dark-room perimetry.

AIR INJECTIONS IN TENON'S CAPSULE FOR LOCATING FOREIGN BODIES

DR. BENJAMIN FRIEDMAN stated that multiple foreign bodies in the globe, orbit and adjacent tissues cannot be localized and differentiated easily by the standard two-plane X-ray exposures. Air is injected into Tenon's capsule and stereoplates are taken with the head in a modified Water's position. The globe is outlined by a pocket of air, and its relation to the foreign body is studied in the stereoviewer. About 6 to 10 cc. of air are injected. There is an average proptosis of the globe of 2 to 3 mm., and

there is an increase in the intraocular pressure of 8 to 10 mm. Hg (Schiotz). This method is contraindicated in cases of recent perforations of the globe; extrusion of some of the ocular contents might result from the increased pressure. Bone-free dental films of the anterior globe segment may be made while the eye is proptosed.

Discussion. Dr. Joseph I. Pascal asked whether Dr. Friedman had had any experience with the Berman localizer. Dr. Friedman replied that he had not, since this instrument had not been made available to him in the Armed Forces.

ABNORMAL RETINAL CORRESPONDENCE

DR. E. KRIMSKY said that a squint may manifest normal or abnormal retinal correspondence, or the combination. Abnormal retinal correspondence is a latent suppressed tendency on the part of a squinting eye to emulate binocular fixation or projection in association with the fellow fixing eye. This is true even though the corneal light reflex be displaced from the fixational position in the deviating eye.

The displacement of the corneal light reflex from the fixational position suggests squint. Estimation of the deviation on mere inspection by the Hirschberg method is crude and inaccurate. An accurate measurement of ocular deviation is a necessary preliminary prerequisite to the study of retinal correspondence.

The artificial restoration of the displaced corneal light reflex to a fixational position is a dependable method both in the measurement of squint and in the diagnosis of retinal correspondence. Such restoration may be accompanied by the simple prism-reflex test. Additional methods include the photometric stereoscope, the synoptophore, or the anglo-meter.

Discussion. Dr. A. Linksz said that

he agreed with Dr. Krinsky's statement, that the production of identical images on so-called corresponding retinal points is not in itself retinal correspondence. Fusion in the high brain centers is an essential part of the phenomenon called normal retinal correspondence. In practice, the determination of common visual directions of the two foveas is used as an indication of normal retinal correspondence.

The double-image test of Bielschowsky, Tschermak's after-image test, the superimposition of a bird and a cage in the synoptophore are all tests for the determination of common visual direction and not of correspondence. Since the same tests are used in general for the determination of what is called abnormal retinal correspondence. Dr. Linksz emphasized the fact that these tests do not prove fusion, and thus do not prove the presence of retinal correspondence. The fact that, in certain squints, the fovea of one eye and an area other than the fovea in the squinting eye assume common visual direction cannot be denied. However, it has not been proved and Dr. Krinsky has not submitted any evidence to support the assumption that these two areas actually contribute to a fused mental image. Dr. Krinsky has, therefore, failed to prove the existence of an anomalous retinal correspondence.

Dr. Krinsky (in closing) said that the best way to determine abnormal retinal correspondence is with the aid of satisfactory artificial illumination, which enables one to observe the corneal light reflex. Such illumination can be employed with the prism-reflex test, the photometric stereoscope, the synoptophore, or the angiometer.

There are some who do not recognize the existence of fusion in abnormal retinal correspondence. If one thinks of fusion in terms of critical binocular fixa-

tion, then that would be correct. However, there are different degrees of fusion and the type found with abnormal retinal correspondence is a rudimentary macular-paramacular type associated with some relative suppression in the area of such correspondence.

CLINICAL PROGRAM
(Presented by the Staff of Children's
Memorial Hospital.)

MICROPHTHALMOS WITH CYST

DR. RICHARD C. GAMBLE presented a male infant who was first seen in May, 1945, when four months of age. The right eye was very small and turned upward. It was well formed and had no coloboma of the iris. No coloboma of the choroid could be seen, but fundus examination, even under anesthesia, was difficult. There was a purplish swelling of the temporal half of the lower lid, about 15 mm. in diameter. The left eye was normal externally but had a small coloboma of the choroid below the disc.

On June 1st, the cyst was aspirated through the skin of the lower lid and 3 cc. of thin yellow fluid were removed. The swelling disappeared at once and the eyeball came down to a normal position. The cyst was aspirated in this manner every few weeks until October 18th, at which time the eyeball and the cyst were removed. So far as could be determined there was no communication between the

interior of the eye and the cyst. Methylen blue was injected into the cyst which aided considerably in its removal, inasmuch as the wall was very thin and it was difficult to differentiate it from the other tissues. The cyst has not returned since the operation.

PTOSIS WITH NEUROFIBROMA OF UPPER LID

DR. RICHARD C. GAMBLE said that this five-year-old girl was born with the right upper lid drooping and thickened. She had café-au-lait spots on the body. X-ray studies of the optic canals were negative. She had had four applications of radium to the lid with a moderately good result. There was marked anisometropia. Vision, with correction, was: R.E., with a $-8.00D.$ sph. $\ominus -150D.$ cyl. ax. 170° , 15/200; L.E., $-2.00D.$ cyl. ax. 165° , 20/30. Discs were normal. She had worn a ptosis crutch since February, 1944, but vision was still poor in the right eye.

PTOSIS AND POSSIBLE NEUROFIBROMATOSIS OF EYELID

DR. RICHARD C. GAMBLE presented a girl, aged six years, who was first seen in January, 1945. The right eye was normal. The left upper lid had drooped since she was two years of age and was swollen and boggy. The left superior rectus muscle was paretic. A café-au-lait spot was present on the back. X-ray studies of the optic canals were negative. A ptosis operation was not advised because it was thought that the upper lid might develop more evidence of neurofibromatosis. So far this has not occurred. The condition at present is essentially as it was one year ago.

METALLIC FOREIGN BODY IN VITREOUS

DR. RICHARD C. GAMBLE said that this 12-year-old boy sustained an injury to the left eye when he exploded a dynamite

cap on August 25, 1945. He was first seen on September 10, 1945. The right eye was normal and had 20/15 vision. The left eye had 20/50 vision. There was a scar in the cornea near the limbus at the 3-o'clock position, the iris root was torn at this point, and there was a slight lens opacity. A shiny, metallic-appearing foreign body was present in the vitreous, down and temporalward. X-ray pictures showed several dozen small foreign bodies scattered through the face.

At present, vision in the left eye is 20/15. There is a slight greenish haze in the anterior lens capsule, but there is no evidence of any inflammation about the foreign body in the vitreous.

SYMPATHETIC OPHTHALMIA

DR. RICHARD C. GAMBLE said that this 39-year-old man received a severe contusion of the left eye on November 19, 1945. There was a rupture of the sclera above the cornea which was covered by conjunctiva. The anterior chamber was filled with blood. The lens was under the conjunctiva on the nasal side of the cornea. Since the lens had not absorbed, it was removed on December 4th through a small incision in the conjunctiva. Penicillin was given for a week immediately after the injury. The left eye was in relatively good condition by January 9, 1946, and very little congestion was present. Vision was: R.E., 20/15; L.E., 20/200. The right eye showed slight ciliary congestion, the pupil was small, vision was still 20/15. No precipitates were seen in the cornea. Sulfathiazole was ordered, and on January 25th the left eye was enucleated. Microscopic sections showed typical sympathetic ophthalmia.

The pupil of the right eye did not dilate well with atropine, but dilated widely with 10-percent neosynephrin, and the dilatation was maintained by atropine. Penicillin and sulfathiazole were used, but the

latter had to be discontinued because of fever and rash. At the present time the vision in the right eye is 20/15. There are a few precipitates in the cornea, the iris is mobile, the media are clear, and there is very little congestion.

TREATMENT OF AMBLYOPIA EX ANOPSIA

DR. W. SEGALL presented several successfully treated cases and explained the method now used at Children's Memorial Hospital in treatment of these cases. Coöperation of parents and children is essential. Amblyopia ex anopsia is not the result of an anatomic defect in visual structures, but has a physiologic etiology. The affected eye is retarded in its function but, up to a certain age, can be brought to normal or practically so. After the eighth year, the chances for improvement are usually slim, although occasionally, under proper supervision, vision in a 10-year-old child has been improved.

Routine examinations are given. These include a vision test, if possible; examination of the external eye, eye movements, the squint, the media, and the fundus; and atropine refraction and the prescribing of glasses. If the vision cannot be tested, the squinting eye should be treated as an amblyopic eye, especially if it stays in eccentric fixation and if the squint is monocular. The near-vision test seems to have some prognostic value. Improvement in near vision is noticed earlier than in distant vision. If both near and distant vision remain equally poor, the prognosis is not favorable. Covering is most important, and constant covering appears to be the most effective treatment.

While treatment in the out-patient department was only partly successful in a number of cases, attendance at sight-saving classes brought striking results in

a relatively short time. This may be because proper supervision is given in the schools and is not given at home. The close work given at school, in properly illuminated classrooms and with proper teaching equipment, is especially useful. If the sight-saving classes were started at the kindergarten age, the number of successfully treated cases would undoubtedly increase.

As a rule, children tolerate the cover well if vision improves quickly. The eye is kept covered for as long a time as benefit can be noted. After the desired result is obtained, the cover is worn part time for a certain length of time. Sudden interruption in the wearing of the cover may reverse the good results achieved. The full correction given in all cases has a good effect on the squint, but the amblyopia persists. The disappearance of squint sometimes leads the parents to believe the child has been cured. If treatment is not continued, however, vision in the squinting eye usually deteriorates. Covering the good eye, with full correction in the poor eye, has been advised with the idea of treating both conditions at the same time. However, it seems most important first to correct the amblyopia by constant cover, and then to take care of the squint later. The good eye is watched carefully to guard against development of amblyopia. Children attending sight-saving classes are examined every two months, younger children much oftener.

SCIENTIFIC PROGRAM

WILLIAM S. GRAY (by invitation) gave a paper on "The Reading Problem," and JOSEPH TIFFIN (by invitation) spoke on "Some Visual Problems of Modern Industry."

Richard C. Gamble,
Secretary.

NEW ENGLAND
OPHTHALMOLOGICAL
SOCIETY

April 16, 1946

DR. HOWARD F. HILL, *presiding*STUDIES ON EXPERIMENTAL EXOPHTHAL-
MOS

DR. GEORGE K. SMELSER read an interesting paper on the above subject. Dr. Smelser said that the cause of clinical hyperthyroidism and its accompanying exophthalmos had not been proved but that the anterior hypophysis was suspected, because administration of extracts of this gland to animals reproduced all of the characteristics of the disease. There is much evidence that the thyroid is not the cause of the exophthalmos; for example, in a large proportion of cases thyroidectomy does not cure but aggravates the ocular symptoms. Exophthalmos of this sort is also much more easily produced in thyroidectomized animals than in those in which the thyroid is intact. Furthermore, thyroxin administration inhibits the production of exophthalmos. The sympathetic nervous system and smooth musculature of the lid and orbit, which undoubtedly affect the width of the palpebral fissure in the hyperthyroid patient, are not responsible for the exophthalmos caused by pituitary injections. The protrusion of the eye is due to swelling of the retrobulbar tissues. Both the orbital fat and the extraocular muscles are edematous, and the edema fluid contains considerable protein. The histologic condition of these tissues is extremely similar to that seen in human cases of postthyroidectomy exophthalmos. Analysis of these tissues in experimental animals showed that in exophthalmos the lipid content of the fat tissue

was unchanged and that the increase in the weight was due to water and connective tissue. The increase in muscle weight was also due to its water content, although there was some true muscle hypertrophy involved.

There are four major facts which may be involved in edema formation. Of these, the last two may be operable in exophthalmos. (1) Any increase in capillary pressure is probably offset by the increase in orbital-tissue pressure which occurs in exophthalmos. (2) There is no evidence of a decrease in the osmotic pressure of the blood (protein content) in exophthalmic animals or human beings. (3) Possibly the edema occurs because the permeability of the capillaries of the orbital fat becomes increased. Preliminary experiments with dyes and the protein content of the edema fluid suggest this possibility. (4) The drainage of interstitial fluid is poor in the orbit, for lymphatics are apparently lacking in this region. These last two factors seemed to be responsible for the edema and to be the cause of exophthalmos.

The edema may be the cause of more than just the swelling of the orbital contents for the circulation of blood in edematous tissues is impaired. This probably makes less oxygen available. The oxygen consumption of the eye muscle is very great and, furthermore, does not decrease appreciably following thyroidectomy. It seems possible, therefore, that the eye muscles in exophthalmos are handicapped by a relatively meager oxygen supply which would be reflected by their poorer function, an observable clinical fact. This weakness of the eye muscles would tend, in turn, to increase the exophthalmos secondarily.

Dr. Mahlon T. Easton,
Reporter.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*,
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois*; Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE SPRING MEETINGS, 1947

The American Ophthalmological Society held its 83rd annual meeting on June 5th, 6th, and 7th, at its favorite site, the Homestead, Hot Springs, Virginia. There were 113 members and 33 guests registered. Sir Stewart and Lady Duke-Elder from London were also present and renewed American friendships of previous years.

As usual, the program was varied; 23 papers were read and were actively dis-

cussed. It is always difficult to single out the most outstanding papers on the program of this Society, but that of Dr. Gordon M. Bruce on "Eye Changes in Pheochromocytoma of the Adrenal Gland" was ably presented and novel. Dr. A. B. Reese's paper on "The Significance of the Base Pressure in Primary Glaucoma" contained the interesting conception that the base pressure in this disease should be one of the criteria upon which should rest the decision of the type of operation re-

quired. The remainder of the program was good, and several other papers are noteworthy.

Dr. Henry C. Haden was elected president, and Dr. Bernard Samuels, vice-president. A particularly happy event of the meeting was the bestowal of the Society's highest honor, the Howe Medal, upon Dr. Lawrence T. Post, consulting editor of the JOURNAL, for distinguished service to ophthalmology. The Society voted to hold its 1948 meeting at Hot Springs, and the date will be announced later.

On Tuesday, June 10th, the Association for Research in Ophthalmology held its 16th annual meeting at Atlantic City. There was excellent attendance, and one of the best of the Association's programs was presented. Instead of the usual 10 papers, 12 papers were read, all of them of much scientific interest and value. The papers by V. Everett Kinsey on "The Transfer of Ascorbic Acid and Related Compounds Across the Blood-Aqueous Barrier" and that by Dr. Alson E. Braley on "Virus Studies in Lymphomatoid Disease of the Ocular Adnexa" were particularly worthy of attention.

A silver bowl, suitably inscribed, was presented by the Association, through Dr. Walter B. Lancaster, to Dr. Conrad Berens in appreciation of his great service in founding the Association. Dr. Phillips Thygeson is the next chairman and Dr. Brittain Payne the new trustee. Dr. James Allen was elected secretary-treasurer.

The Section on Ophthalmology, American Medical Association, joined in the centennial celebration of the parent organization in Atlantic City, in a delightful and friendly session. Sir Stewart Duke-Elder was the Foreign Guest of Honor, delivering a superb address on the "Nature of Intraocular Fluids." Dr.

Frederick Verhoeff, the American Guest of Honor, gave the centennial address of the section on "American Ophthalmology During the Past 100 Years," in which he developed the historic stages of progress of our great specialty, detailing events and personages in his usual entertaining fashion. The chairman of the Section, Dr. Derrick Vail, gave as the subject of his address, "The Prestige of Ophthalmology."

Besides these special addresses, 14 scientific papers with excellent discussions were read. The quality of the program was outstanding, and each of the presentations was noteworthy. An exceptionally large number of the Fellows and members of the section were present. There were also other distinguished foreign guests present, among them Professor Arganaraz of Buenos Aires, Argentina, and Dr. Tomas Yanes of Havana, Cuba. The scientific exhibits of the Section received much favorable comment.

Sir Stewart Duke-Elder received the Research Medal of the Association for his outstanding scientific and literary researches of great value to patient and physician. That it was an exceedingly popular choice of a recipient of this great honor, was shown by the sustained and spontaneous applause by those present.

The newly elected officers of the Section are: Dr. Everett Goar, chairman; Dr. Francis H. Adler, vice-chairman; and Dr. Trygve Gundersen, secretary.

The Atlantic City meetings were saddened by the sudden death of our colleague and friend of each one of us in American Ophthalmology, Dr. Edward C. Ellett of Memphis, Tennessee, who died of coronary occlusion on his arrival at Atlantic City on June 8th. None of those who were with him in Hot Springs and heard his vigorous discussions of several of the papers there, had the slightest idea

that he would be taken from our midst so soon and so abruptly. His loss to American ophthalmology is a very great and severe blow, and we mourn grievously.

Derrick Vail.

EYE BANKS

It is time to "Stop, Look, and Listen," to evaluate keratoplasty, and to consider the tremendous publicity that has recently surrounded the subject.

After the report of one failure of corneal transplant over 100 years ago and one success about 50 years ago, the subject lay dormant until its resurrection some 35 years later. At that time, several investigators became interested anew and, applying modern techniques, began to have some successes. Shortly thereafter this dramatic idea reached reporters who seized on it and publicized it avidly. Uncritical as most people are in fields other than their own, seeing a gold mine wherever one nugget is uncovered, corneal transplant meant to them an eye for an eye, a good one for a bad, and hope stirred in the mind of every blind man. Philanthropic individuals and organized charity were quickly aligned to be of service but the laity has almost taken over.

Firstly, what is the probable number of those who might be helped by corneal transplants? The estimates in the press varying from 10,000 to 40,000 surely paint a greatly exaggerated picture. A recent letter from one eye bank suggests that 15,000 of the 250,000 blind in this country would be benefited by keratoplasty. Can this possibly be true? Apropos of this, a careful survey of pupils in the St. Louis School for the Blind recently did not reveal a single case. A review of those on the pension rolls for the blind in Missouri has also apparently been fruitless. The operation itself is not extremely

difficult. Any competent eye surgeon should be able to perform it and many eye surgeons have stood ready and waiting for suitable cases but, for the most part, the cases haven't appeared. Only a few hundred corneal transplants have been performed in the United States and already there are indications that the first crop has been harvested.

Of the operations thus far performed, perhaps somewhat because of inexperience and a desire to improve technique and to learn just what cases were amenable to betterment, many have proved futile and some definitely ill advised. Actually, we may ask what percentage of them showed significant value to the patient. The answer is not known, but from conversation with some of those most active in this kind of work, 25 percent would be a generous estimate. Frankly, therefore, we are dealing with a very restricted field, although important to the individual affected, and one that should undoubtedly be investigated but need not be over-emphasized. Nothing herein written is intended to belittle or detract from the studies being made to improve techniques or the efforts to train ophthalmologists to perform keratoplasties. Both are highly desirable and their encouragement is a valuable contribution to the advancement of knowledge and the general welfare. These efforts should be continued and by no means discouraged.

Obviously, donor eyes are needed. How can they be best obtained? The idea of eye banks occurred to someone, based perhaps on the invaluable blood banks brought so keenly to the attention of the public during the recent war. Let us consider for a moment possible sources and handling of donor material. Unquestionably, present methods may and probably will be improved but, as of the moment, the best material is fresh eyes or those

after removal not more than three days previously. Then, too, the eyes obtained from cadavers must be enucleated within a few hours after death and be placed in a container at a few degrees above zero (centigrade) and shipped to the surgeon. The function of the eye bank is to interest possible donors and to store and distribute material. Actually, how do banks function? Almost every reader has heard about eye banks so that those in charge of them receive many inquiries as to how one may leave his eye for scientific purposes. Forms are sent to inquirers advising them how to act but between that and the accomplishment of their purpose lie not only the continued life of the individual but the physician attending at the time of death who must immediately enucleate the eyes, the lawyer who must be aware of the request in the will, the undertaker who is usually very unsympathetic to the idea because it makes injection more difficult, and the nearest of kin who legally controls the disposition of the body. Then, too, suitable containers for the eyes and methods of transport are difficult to obtain unless one has made advance preparation for the event, so the net result from such inquiries is close to zero. However, eye-bank organizations in a few large cities have been successful in serving as intermediaries in getting enucleated eyes for transplant purposes.

Probably the best way is to have available forms of bequest to which the attention of each patient entering the hospital is drawn in the hope that he or she will donate his or her eyes in case of death in the hospital. An ophthalmological staff that has been advised of how to act in case of death of these patients, how to enucleate, and how to block the orbits so that the injection fluid will not seep out, and that has made an arrangement in advance with the undertaker, can then

occasionally obtain transplant material. By this method also more valuable eyes for pathologic examinations may be obtained. And this is a most important point because it may help solve the always difficult problem of getting eyes of deceased patients, whose cases have been interesting, for pathologic study. Indeed, a little over-publicity of corneal grafts might be excused to accomplish this good purpose.

One should applaud the efforts of organizations to obtain material for transplants, but these organizations should attempt to make the public aware of the true situation and should not indulge in gross exaggerations. The publicity has been so great and some of it so ill considered as often to hold out hope where there is no hope. By constant use of newspapers, magazines, and radio talks the procedure has been over publicized and is making the whole matter ridiculous in the eyes of the profession.

Among the latest outbursts on the subject is one by a proposed new organization addressed to some 18 well-known ophthalmologists who have been selected as surgeons capable of performing this "delicate operation of corneal transplantation." It goes on to state that "Preparations have been made for many nationwide broadcasts to select blind patients to be operated upon as outlined in the enclosed letter being mailed to specialists in over 500 cities. The radio editors request that for this first program we shall interview on the air someone who has had his or her sight restored and then allow that person to select the next patient with all expenses guaranteed.

"To say that your coöperation is desirable is a magnificent understatement. Each of you in your own city is the very life blood of the ——— (name of organization deleted by this writer). Without you we simply cannot exist. You are the

only ones who can perform the operation. We believe our objective is one of the most noble ever attempted. If we are to survive, we must request from you the performance of two minor duties: First—Personally seek out and urge every person you know who has had their sight restored to write an interesting story about themselves to our radio editors. The surgeon's name will not be publicized. The winner will receive a wonderful trip to New York City. Second—Examine and screen out the blind in your city to obtain possible future patients for our sponsors. It is preferable that each person be examined by at least three specialists.

"Radio time has been offered to us but it must be accepted immediately. Therefore, it is most urgent that your replies be received as soon as possible. Please offer suggestions of possible additions to our list of surgeons who perform this specialized operation. Your confidence will be respected. In closing may we respectfully suggest that several thousand patients divided among the small but very exclusive group of surgeons will bring not only personal pride of achievement but considerable revenue to each surgeon as well."

The intent behind this letter may be of the best but certainly the professional advice is not such as to inspire confidence.

There is also an "open" letter accompanying the above that is much too long to quote. The financing of the surgical expense of these patients is to be solicited from 150 of America's leading advertisers.

A comprehensive symposium on keratoplasty is to be held at the meeting of the American Academy of Ophthalmology and Otolaryngology in Chicago in October and it is to be hoped that we shall learn much more about the entire subject. Let us have "The truth, the whole truth, and nothing but the truth."

Lawrence T. Post.

THE BICENTENNIAL OF CATARACT EXTRACTION

On April 8, 1747, Jacques Daviel called to operate on M. Garion, a master wig-maker, whose cataracts appeared very favorable for surgery. Nevertheless, the expert Daviel was unable to depress either lens. At that moment he decided on a deliberate extraction. After widely opening the right cornea, he passed a small spatula through the pupil and extracted from the posterior chamber the entire lens, the capsule of which had been divided by his previous interventions. Though some vitreous was lost, the patient made an uneventful recovery; and with a cataract glass read accurately. Thus was initiated the first significant advance in cataract surgery since the invention of couching by the legendary Susruta sometime about 1000 B.C.

Accustoming himself gradually to the new operation, Daviel came to the firm decision three years later to operate for cataract only by extraction. Of a total of 240 extractions, Daviel classified 33 as failures, but the standard of success then current included all whose postoperative vision allowed walking without a guide. In his claim for priority, Daviel stressed that the idea of extraction logically followed an appreciation of the true nature of cataract, a concept which was accepted only after Brisseau's demonstration in 1705. The lens had been previously assumed to be the seat of vision, hence the scriptural expression "precious as the apple of the eye." After Daviel's communication, his formidable operation was further popularized by Baron Wenzel who admitted destroying a hatful of eyes before achieving the requisite skill. Success demanded of the surgeon "a lady's hand, an eagle's eye, and a lion's heart."

In the century that followed the pros and cons of couching and extraction were ardently debated as each procedure was

somewhat improved. In 1772, Percival Pott, a proponent of couching, gained from his experience the conception of discission as a distinctive method of dealing with soft cataracts, and Saunders, 30 years later, demonstrated its special value in operating on children. Von Willburg, in 1785, gave couching a new lease of life by changing the maneuver from depression to reclination.

A hundred years ago, although extraction was gaining favor in Europe, reclination was still preferred in this country, being advocated by Edward Delafield, a founder of the New York Eye and Ear Infirmary, as the more successful procedure—a view strongly shared by his famous contemporary, Argyll Robertson, and many others. Some conservative surgeons attempted to avoid the evils of depression and the dangers of extraction by performing repeated discissions in most cataracts—Jacobs up to the age of 50 years, and Stevenson even included in his report a woman, aged 91 years.

At this impasse, von Graefe, whose skill and insight were universally acknowledged, pondered on improvements of technique that would make the Daviel operation less hazardous. The result was his peripheral linear section. His stimulating contributions intensified the interest in extraction, and secured its definitive acceptance even before the advent of asepsis and local anesthesia removed the dangers that von Graefe had sought to circumvent. Indeed, his innovations, except for the von Graefe knife, were finally abandoned.

From the time of Daviel the safe intracapsular removal of the cataractous lens has been the dream of the ophthalmic surgeon. The reckless technique of the

Pagenstechers won few disciples, but increasing popularity came with the methods of Smith, Barraquer, and Stan-culeanu. Finally the introduction of various safety measures including akinesia, superior rectus control, corneoscleral sutures, and retrobulbar anesthesia, coupled with the enthusiastic sponsorship of Knapp, Elschmig, Grosz, Sinclair, Arruga, and Manes, at long last established the intracapsular operation as the generally preferred procedure of modern cataract surgery.

Fifty years ago Herman Knapp in an analysis of a large series of cataract expressions by qualified operators found that 85 percent of the results were successful, his standard being postoperative vision of 20/200 or better. In 1,000 intracapsular extractions reported in 1944, again 85 percent were considered successful, but the standard now was a postoperative vision of 20/30 or better. In 5 percent of the cases, vision was annihilated through postoperative complications—hemorrhage, iritis, vitreous loss, corneal dystrophy, glaucoma, retinal detachment, and in one case, infection. Beneventus Grassus in his *Practica Oculorum*, the first incunabula on the eye, began and ended his operations with a prayer. In the silence of his soul what surgeon of today dare do otherwise!

Only slowly has ophthalmology realized its measure of indebtedness to Daviel. His grave is in the cemetery of the Grand Saxonix Church, two miles north of Geneva, Switzerland, but not until 1885 was a suitable memorial placed at this shrine.

James E. Lebensohn.

OBITUARY

WALTER IVAN LILLIE
(1891-1947)

When Walter Ivan Lillie died suddenly of a heart attack at his home on February 21, 1947, the medical profession lost one of its best known and most respected ophthalmologists.

DR. WALTER IVAN LILLIE

(Photograph © Fabian Bachrach.)

Born on November 5, 1891, in Grand Haven, Michigan, Dr. Lillie was the third of four sons of Walter Irving Lillie and Ella McGrath Lillie. After his graduation from the Grand Haven High School in 1909 he entered the University of Michigan from which he received the degree of Doctor of Medicine in 1915. He interned at the University Hospital, Ann Arbor, Michigan, and from there went to the Buick Emergency Hospital, Flint, Michigan.

Walter Ivan Lillie became a fellow in ophthalmology on the Mayo Foundation on July 1, 1917, and was made assistant in ophthalmology in the Mayo Clinic. On August 11, 1917, he volunteered for military service and was assigned to active duty for a six weeks' course at the Psychopathic Hospital in Ann Arbor. On September 29, 1917, he was appointed examiner in neurology and psychiatry at Base Hospital with the 37th Division, Camp Sheridan, Montgomery, Alabama. On February 14, 1918, he was attached to the British Army in England. There he took care of shell-shocked cases in the 4th London General Hospital, British Expeditionary Forces. On April 29, 1918, he was made assistant division psychiatrist with the 41st Division, American Expeditionary Forces, St. Aigmon. He continued in the neuropsychiatric service of the American Expeditionary Forces at the First Depot Division and Base Hospital 117. Beginning February 4, 1919, he conducted examinations of command for mental and nervous diseases at Camp Meigs until he was separated from the service on March 10, 1919. After his release from the Army he resumed his fellowship on the Mayo Foundation and received the Master's Degree in Ophthalmology in 1922. He was made an instructor in ophthalmology on the staff of the Graduate Medical School in the Mayo Clinic and by 1927 had been advanced to associate professor of ophthalmology on the Mayo Foundation.

In November, 1931, Dr. Lillie traveled to Shikarpur, India, to serve with Dr. H. T. Holland at his large ophthalmic surgical clinic for a two-month period. After his return by way of the Orient in March, 1932, he continued his work at the Mayo Clinic.

Dr. Lillie was appointed professor of ophthalmology and head of the depart-

ment at Temple University School of Medicine in September, 1933. He became consulting ophthalmologist at Temple University Hospital and Shriners Hospital, Philadelphia, and at Norristown State Hospital, Norristown, Pennsylvania; and guest lecturer in neuro-ophthalmology, Graduate School, University of Pennsylvania.

On August 30, 1916, Dr. Lillie married Miss Opal C. Jones at St. Johns, Michigan, who with one son, Robert J. Lillie, survives him. Philip M. Lillie, a second son, served in the Army Air Forces and was killed on a training flight on July 31, 1944. Dr. Lillie is also survived by a granddaughter and three brothers.

Dr. Lillie was a member of the American Medical Association, the American Academy of Ophthalmology and Otolaryngology, the American Ophthalmological Society, the American College of Surgeons, the Philadelphia College of Physicians, Sydenham Medical Coterie, the Harvey Cushing Society, and Sigma Xi. He was a regular attendant at the meetings of the medical societies, both local and national, of which he was a member.

Whenever Dr. Lillie appeared on a program, he made an outstanding contribution, not only because of his unquestioned authority and ability, but also because of his direct approach and enthusiastic presentation. Although his national reputation was primarily based on his presentations of neuro-ophthalmic subjects, he was equally capable in the fields of surgical and medical ophthalmology.

In addition to contributing greatly to

the success of many medical society meetings, Dr. Lillie was the author of numerous articles dealing with ophthalmology and was co-author of the textbook, *Cardio-Vascular Renal Disease*. He was also a contributing editor of the *Pennsylvania Medical Journal* and *Confinea Neurologica*.

Small-game hunting and trap shooting were his hobbies, and he was a member of the Philadelphia Country Club, the Roxborough Gun Club, and the Atlantic Indians.

Dr. Lillie always saw the brighter side of life and was so sincere and encouraging that he was able to infect others with his own contagious optimism. Even the briefest conversation with him was a tonic. His charm and ability brought him the love and respect of his patients and colleagues, alike.

Although his practice was large and demanding, Dr. Lillie never allowed it to interfere with his teaching and administrative duties. He contributed greatly to scientific literature through his own writings and to the practice of ophthalmology not only through his own participation in that specialty, but also through his active interest in training others to work in that field.

It has been said that the prerequisites for a successful physician are that he be honest, kind, and competent. Such was the way of life for Walter Ivan Lillie, and his passing has left a tremendous void in the lives of his family, friends, and medical colleagues.

P. Robb McDonald.

CORRESPONDENCE

GOOD, BUT NOT GOOD ENOUGH: OUR CHALLENGE

Editor,

American Journal of Ophthalmology:

The recent rapid development of interest in Industrial Vision is bringing to the office of the professional man a new type of patient. This patient is not seeking professional advice because he has become aware of a problem which he believes is associated with his vision or because he considers his vision to be faulty or below the ordinarily conceived normal. He is seeking professional advice because he is unable to compete adequately with his fellow workers on his job in those phases of effort that have to do with seeing skills.

Very frequently it is found that such patients were not originally aware, on the basis of their own observation, that their job difficulty might be due to their vision. The possible relationship between vision and industrial performance is often revealed by various fact-finding methods used by analysts working in and with industry, who have by previous controlled studies ascertained definite and varying patterns of visual skills matching job demands which make for success on the job.

These findings are further scrutinized and evaluated by professional consultants of a plant and are thus approved for use in that plant. An employee whose visual skills do not fit this pattern is directed to a professional man for investigation of his vision. He may not be personally aware that his vision is in need of attention. He has been told that in all probability his work would be better if he were able to receive visual aid.

As would be expected, visual demands in industry are sometimes more deliberately evaluated than are the symptoms which bring the usual patient to the doctor's

office. Ordinarily a patient does not seek advice until his vision is obviously disturbed and he has cause for alarm. In industry, workers are being requested to seek professional assistance before their visual skills indicate serious trouble. They are being urged to visit the professional man when visual disturbances fall into a category where they can be diagnosed only in terms of an increased, although not always obviously recognizable, difficulty in performing the industrial task.

It is, therefore, to be expected that among these industrial patients the proportion of individuals with severe visual defects is much lower than among a random group of ordinary patients. The visual demands of industry are intricate and sometimes the worker whose visual skills fall well within the normal by the usual clinical criteria may nonetheless experience difficulty in performing his job. Where we would normally hesitate to ask a patient to change his lenses if he read 20/20, O.U. for near, so that he could read 20/15, we now need to realize that a job pattern may indeed demand 20/15 and then we must prescribe the change. The same may be true of a symptomless exophoria which nevertheless is found by statistical methods to be improper for a certain job and therefore should receive orthoptic training. Some learn, reluctantly perhaps, that a man can be handicapped in the performance of his job because he may require better than normal eyes.

One job which the authors recently observed in a printing establishment involved the preparation of lithographic plates. These workers were comparing photographic negative plates with original copy for shading of colors and silhouetting. Exact shades of color are obtained by varying the concentration of the dots which in the finished plate will transfer

the color to the page. These dots are so small as to be barely discernible with the naked eye but the worker must obtain the proper concentration (to insure the proper shade) and the proper distribution (to insure proper silhouetting of the picture detail). The worker on such a job must seek "better than normal" eyes. His near visual skills are of greatest importance. By statistical analysis it was found that the best workers on this job showed near-vision acuity equivalent to 20/15 or better, at 13 inches—not at the usual 20/20.

Therefore, workers whose near visual acuity was the equivalent of 20/20 were being referred to professional men for further visual aid (if possible), since their job required at least an equivalent of 20/15. Here the professional man must adjust his usual clinical concept of when to correct acuity further and must prescribe for the best possible acuity. He must recognize the need of some highly specialized workers for extremes of perfection in visual functions.

Similar critical qualities of vision are found necessary for such jobs as hosiery looper, gager of fine parts, assembler of small mechanisms (such as cameras and watches), to name but a few. Among 450 industrial jobs studied by the Occupational Research Center, Purdue University, 10 percent were found to require distant-vision acuity in both eyes better than 20/20; 20 percent were found to require better than 20/25. Among the same group of jobs, 13 percent were found to require acuity better than 20/20 at 13 inches, and 33 percent, or one third, better than 20/25.

These figures illustrate the number of jobs where visual demands are such that workers with normal or near-normal vision may, nevertheless, actually be handicapped to a degree in performing their specific industrial tasks. Furthermore, the standards used by industry are usually *minimum* standards and represent only the vision needed to keep up on the industrial job. For more success and more outstanding performance, even higher visual acuities may often be desirable.

It becomes apparent, therefore, that the professional man treating industrial patients must add to his present task of correcting visual defects—a brand new concept of effort, that of improving visual *skills* which may include one or more factors (especially acuity and muscle balance). The clinical methods of improving these skills are already in use but our attention must be focused more sharply on them. New testing methods and new correcting procedures are being developed to meet the increasing challenge of this task. Our present equipment, especially for near-point problems, is inadequate.

No longer is the professional man responsible only for giving assistance where some obvious clinical impairment is recognized, but he must now seek to provide additional assistance where job demands require raising the workers' visual skills above the category "good" to the one of "best."

Lafayette, Indiana.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

1

GENERAL METHODS OF DIAGNOSIS

Contino, Filippo. A new method of determining pupillary diameter. *Rassegna Ital. d'Ottal.*, 1946, v. 15, Nov.-Dec., pp. 450-460.

The author has constructed an apparatus composed of a telescope and a Lobeck measuring ocular. The chin-rest of the biomicroscope table is used and the measuring device is attached to the movable arm of the same. (2 figures.)
Eugene M. Blake.

Hughes, W. L. A combination red filter and occluder. *Amer. Jour. Ophth.*, 1947, v. 30, May, p. 609.

Owens, W. C. A fixation light for the cardinal directions of gaze. *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 611-613. (9 references.)

2

THERAPEUTICS AND OPERATIONS

Bakker, A. The action of sulphanilamide on rabbits' lenses in vitro. *Brit.*

Jour. Ophth., 1947, v. 31, April, pp. 216-219.

Sulphanilamide, not above the therapeutic level, is quite harmless for explanted lenses of rabbits. When the concentration is elevated, it is noted that the lenses from very young rabbits become opaque; however the toxicity of sulphanilamide for lenses from adult rabbits is less pronounced.

O. H. Ellis.

Cavazzini, Mario. The activity of penicillin in the presence of pupillomimetic drugs. *Rassegna Ital. d'Ottal.*, 1946, v. 15, Nov.-Dec., pp. 518-529.

The extreme lability of penicillin and the fact that such drugs as atropine, pilocarpine, and adrenalin are frequently employed locally at the same time as the penicillin, induced the author to study the effects of such drugs upon therapy with penicillin. The latter is a monobasic acid (pH about 2.8). The miotics, mydriatics, and local anesthetics were introduced into solutions of penicillin in vitro and did not

affect the potency of the antibiotic; nor did the latter exert a baneful effect upon the action of the drugs. No incompatibilities were discovered. (2 figures.) Eugene M. Blake

Cortes, Herman. Results of sulphonamide therapy in ophthalmology. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, July, pp. 664-672.

A detailed study of each patient that was successfully treated with sulphonamide is reported. The lesions were acute and purulent conjunctivitis, corneal ulcers with hypopyon, and metastatic endophthalmitis. The drug used was Albucid (sulfacetamide) and was administered locally and systemically.

J. Wesley McKinney.

Costi, C., and Alvarez Maribona, T. Use of crystalline penicillin in ophthalmology. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, July, pp. 644-663.

The authors report the good results obtained by the local use of crystalline penicillin in acute, subacute, and chronic conjunctivitis, trachoma, acute, subacute, and chronic dacryocystitis, corneal ulcers, and corneal ulcers with dacryocystitis. The detailed study of each patient is described briefly.

J. Wesley McKinney.

Dubois-Poulsen, A. Retrobulbar ciliary neurotomy. Ann. d'Ocul., 1946, v. 179, Nov., pp. 578-590.

As a substitute for enucleation in painful blind eyes, especially in glaucoma, opticociliary resection was abandoned because of severe complications including orbital hematoma and exophthalmos. Destruction of the ciliary ganglion involves a complicated technique and trophic corneal disturbances are not infrequent. Section of the ciliary nerves between the ganglion and the

eyeball is preferable. After canthotomy the conjunctiva is dissected from the limbus above and below and the external rectus is temporarily resected. Arruga's speculum for retinal detachment is introduced and the long ciliary nerves are fixed between two strabismus hooks and cut. The external rectus is replaced and the canthotomy and conjunctiva are sutured with silk. The operation is followed by few complications. The tension after a brief drop may rise to its previous level, but the corneal edema is permanently relieved. Seven illustrative cases which are presented include primary glaucomas and glaucomas following hypertensive retinopathy and venous thrombosis. (27 references.) Chas. A. Bahn.

Duguid, J. P., Ginsberg, M., Fraser, I. C., Macaskill, J., Michaelson, I. C., and Robson, J. M. Experimental observations on the intravitreal use of penicillin and other drugs. Brit. Jour. Ophth., 1947, v. 31, April, pp. 193-210.

The authors present results of experiments on the intravitreal injection of penicillin and other drugs. Commercial penicillin, sodium sulphacetamide, mafenil and V. 335(p-methyl sulphonyl benzylamine) introduced into the vitreous were damaging to the retina to a degree which excluded their use clinically. Sodium sulphacetamide and pure penicillin either together or separately in the vitreous were found to diffuse rapidly into all parts of the eye, and the vitreous acted as a depot for replenishing the drug lost from the other tissues. It was found that pure sodium penicillin was highly effective in the control of infections of the vitreous body, and that chemo-therapeutic levels could be maintained by intravitreal injections of 2000 units every two days. Pure sodium penicillin caused minimal

retinal destruction, and its use seems indicated and justifiable in certain cases of infection. O. H. Ellis.

Garcia Miranda, A. Penicillin in ophthalmology. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, July, pp. 617-643.

The author has made a complete review of the literature on the tolerance of the various ocular tissues for penicillin and the concentration of penicillin in these tissues after various methods of administration. It was found that penicillin reaches the highest concentration in the tissues when it is given locally. Good results were obtained by means of this drug in the treatment of blepharitis, conjunctivitis, keratitis, infection of the uveal tract and some other intraocular septic processes.

J. Wesley McKinney.

Kornerup, Tore. Investigation in variable monochromatic light of the outer vessels of the eye. *Acta Ophth.*, 1946, v. 24, pt. 4, p. 423.

Nine cases of inflammation are reported, in which areas of pericorneal injection were examined in variable monochromatic light. The shifting of the diffusion spectrum at various stages of the inflammation that produced the pericorneal congestion is illustrated with graphs, and is attributed by the author to the marked difference of the diffusion spectrum from arteries and veins. The changes in the diffusion spectrum were different in periods of clinically demonstrable improvement and of persistent inflammatory process. In several cases a change in the diffusion spectrum indicative of improvement preceded the clinical symptoms.

Ray K. Daily.

Matteucci, Pellegrino. The effect of retrobulbar injection of alcohol upon

ocular tissues. *Rassegna Ital. d'Oftal.*, 1942, v. 11, Nov.-Dec., p. 483.

Following the retrobulbar injection of alcohol there may result exophthalmos, chemosis, hypoaesthesia of the cornea, mydriasis and pupillary torpidity, corneal alterations, variations of tension and vasodilatation of the vessels of the orbit, uvea and retina. The optic nerve does not present appreciable histologic alterations. Injection of over 70 percent solutions of alcohol should be given guardedly where vision is good or any corneal change exists. The treatment is limited to patients with absolute or hemorrhagic glaucoma, where severe pain is present. The reduction of tension in glaucoma is not sufficient to warrant the injection in acute or chronic simple glaucoma. Vasodilatation sometimes follows and weak concentrations of alcohol may be employed in iridocyclitis with hypertension. In experimental animals the vasodilatation was evident in microscopic sections of the optic nerve, retina and orbit. (4 figures.)

Eugene M. Blake.

Rosengren, Bengt. On the depth of cauterization in surface diathermy, with special reference to amotio operations. *Acta Ophth.*, 1946, v. 24, pt. 4, pp. 389-416.

Investigations in which cattle liver was used as test material showed that the depth of cauterization is influenced by several factors. It is increased if the water content of the surface is high. It is greater if diathermic coagulation is performed with a weak current acting for a longer time, than with a strong current acting for a shorter time. It increases with the size of the electrode. If the degree of moisture in the surface, and the time of coagulation are standardized, it is possible to regulate the

depth effect quite accurately by using different sizes of electrodes. The author found that an even and adequate penetration is obtained when he uses a ball electrode 1.25 or 1.00 mm. in diameter on a slightly damp scleral surface, and when pergmentization appears in 2 to 3 seconds. (5 illustrations.)

Ray K. Daily.

Vannas, Mauna. On the use of rib cartilage grafts for correction of cosmetic defects caused by enucleation. *Acta Ophth.*, 1946, v. 24, pt. 3, pp. 225-237.

After a brief review of the literature on the various type of implants used after enucleation, Vannas reports the technic of implantation of rib cartilage that is covered by perichondrium. On the basis of 36 operations, he regards this as the most satisfactory implant material. The implant is covered with a pouch that is made with the help of catgut suture, over which the four rectus muscles are tied with catgut. The conjunctiva is closed with silk. The perichondrium is expected to prevent absorbtion of the cartilage. To correct retraction of the upper lid Vannas uses implantation of perichondrium, with almost no cartilage. From the free end of the patient's lower rib a piece of cartilage 3 cm. in length is excised; it is split longitudinally, and almost all the cartilage is removed; the two thin plates of perichondrium are placed against each other, surface outwards. A vertical incision 1 to 1½ cm. in length is made lateral and superior to the external canthus, and a shorter incision is made nasally. With curved scissors an arch shaped space as high as possible under the supercilium, and under the fibers of the orbicularis is prepared, and the implant is pulled into it by a clamp introduced through the nasal incision.

Since retraction of the upper eyelid is unpredictable, Vannas suggests that at the time of enucleation a piece of cartilage be excised, and buried subcutaneously in the chest wound, to be easily available if required later.

Louis Daily, Jr.

Wofflin, E. A new procedure for extraction of intraocular nonmagnetic foreign bodies. *Ann. d'Ocul.*, 1946, v. 179, Nov., pp. 591-593.

Some amalgams have the power of adhering firmly to metals on contact. In the author's experiments with this ingenious idea, he used copper, silver, and sodium amalgams on very fine rods to remove zinc, copper, and aluminum foreign bodies imbedded in gelatin that had the consistency of human vitreous. Animals' eyes were also used in these experiments. The amalgam of sodium solidified faster but was possibly irritating to the human eye, although not to the eyes of guinea pigs. Five minutes or more of contact was necessary for a suitable catalytic adhesion. The amalgam must solidfy at the normal temperature of the human vitreous. The author desires to interest other ophthalmologists in the experimental development of the ophthalmic use of amalgams, especially in the removal of intraocular nonmagnetic foreign bodies.

Chas. A. Bahn.

3

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Bárány, Ernst. A theory of binocular visual acuity, and an analysis of the variability of visual acuity. *Acta Ophth.*, 1946, v. 24, pt. 1, pp. 62-92.

The literature is reviewed, and the causes of the variability of instantaneous visual acuity discussed. The method used in this investigation is

described in detail; it consisted essentially of instantaneous exposure of Landolt rings, with a rotating apparatus, under a standard illumination, and with an apparatus which was equipped with automatic regulation of the exposure time. The average instantaneous acuity variability in about 30 eyes was found to be ± 20 to 25 percent of the visual acuity value. A new explanation is advanced for the higher visual acuity even in emmetropic subjects when both eyes are used. It is based on the assumption that the instantaneous acuity fluctuations are due mainly to causes individual for each eye, and that consequently when both eyes are used one eye can see well at the instant when the other eye sees badly. No central cooperation beyond this random inter-complementing is assumed. The mathematical calculations of these assumptions agree with the experimental results, and indicate that the cerebral factor is not significant.

Ray K. Daily.

Eames, T. H. A study of tubular and spiral central fields in hysteria. *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 610-611. (9 references.)

Koch, Walter. An improved dark-adaptometer. *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 235-237.

A redesigned and improved dark-adaptometer is presented. Filters of different colors can be brought into position as well as neutral filters for altering the intensity of light. The instrument allows for a wide range of readings on patients with gross disturbances of dark adaptation.

O. H. Ellis.

Mandelbaum, J., and Sloan, L. L. Peripheral visual acuity: with special reference to scotopic illumination.

Amer. Jour. Ophth., 1946, v. 30, May, pp. 581-588. (1 table, 2 figures, 7 references.)

Martin, L. C., and Pearse, R. W. B. The comparative visual acuity and ease of reading in white and colored light. *Brit. Jour. Ophth.*, 1947, v. 31, March, pp. 129-144.

These experiments were performed to determine differences in visual acuity and in ease of reading in white and in red light. A view box was designed in which all factors remained constant including the intensity of the white or red light. The test object was a slide on which was printed a grating with 55 lines to the inch. The general levels of illumination used were approximately 0.06, 0.6, 6.0 foot candles. The tests were binocular and the observers varied in age from 14 to 50 years. The results are recorded in detail in tabular form. They indicated that among the lower levels of illumination, red light was as much as 80 percent more efficacious than white and at the higher levels there was little practical difference.

In studying the ease of reading the observers were made to read separate, plainly printed words in varying intensities of white and red light and the numbers of words read were recorded. There was little practical difference, although white was probably better in higher levels and red better in lower levels. A third and purely subjective test of simply having the observers read for 30 minutes by the two lights and describe differences in ease and comfort revealed again no appreciable differences.

Morris Kaplan.

Stomberg, A. E. The psychology of the squinter. *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 601-606. (6 references.)

4

OCULAR MOVEMENTS

Carelli, P. V. **Relation of the near point of convergence to squint surgery.** *Illinois Med. J.*, 1947, v. 91, March, pp. 124-126.

Primary divergence insufficiency should be treated by surgery on the external rectus muscles. Accommodative convergence excess should have a trial period of glasses and atropine, whereas a moderate recession of the stronger internal rectus is indicated when there is no accommodative factor.

Irwin E. Gaynon.

Cojazzi, Luigi. **Acoustic phenomena provoked by ocular movements.** *Riv. Oto-Neuro-Oft.*, 1943, v. 3, May-June, pp. 165-174.

A 25-year-old man developed signs of arachnoiditis of the posterior cranial fossa after a radical operation performed for otitis media of his left ear. Gaze to his left was accompanied by a noise of constant pitch inside the left ear which disappeared when the eyes returned to the primary position. The author discusses the explanations offered in the literature for this rare phenomenon and assumes that in his case an irritation of the vertebral sympathetic vasomotor system was responsible for the noises. K. W. Ascher.

Levit, L., and Giqueaux, R. **Supranuclear ophthalmoplegia.** *Anales Argentinos de Oft.*, 1946, v. 7, July-Aug.-Sept., pp. 75-78.

A twelve-year-old child is presented with a history of encephalitis at the age of eight months. At the present time there is a total peripheral facial paralysis, more marked on the right side, a right lingual hemiatrophy, and loss

of all conjugate eye movements. The lesion is believed to be supranuclear and probably in the posterior longitudinal fasciculus. Edward Saskin.

Malbran, Jorge. **Etiopathogenesis and therapeutics of strabismus.** *Arch. Chilenos de Oft.*, 1946, v. 2, March-April, pp. 95-104.

This well-written article of ten pages deals especially with the problem of amblyopia in relation to prognosis from treatment, and with the surgery of the condition.

W. H. Crisp.

Suarez Villafranca, Manrique. **Surgery in strabismus.** *Arch de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, July, pp. 676-686.

In the surgical treatment of strabismus the author performs partial tenotomy of the inferior two-thirds of the antagonistic muscle and spreads the untouched fibers. With this technique he obtained good results in 75 percent of patients. The other 25 percent (deviations over 7mm.) showed slight hypocorrection of one and a half millimeters. In these patients tenotomy of the muscular fibers untouched in the first operation was done. Of 47 patients, 41 had convergent squint and 6 divergent. This method failed in only three. CONJUNCTIVA

Colombo, G. L., see Luiggi, Gan, this section. Prof. Colombo of Milan has informed us that the *Ann. d'Ocul.* inadvertently credited his article to Gan Luiggi (Colombo), instead of Gian Luigi Colombo.

Luiggi, Gan. **Rickettsia in nummular epidemic conjunctivitis.** *Ann. d'Ocul.*, 1946, v. 179, Nov., pp. 594-596.

It is probable that conjunctival Rickettsial diseases vary greatly in their pathologic and clinical patterns. In a patient with acute epidemic conjunctivitis the bacterial findings were negative, but Rickettsial bodies were present. The technique included alcohol-ether fixation for 5 hours, Giemsa staining for 24 hours and subsequent rinsing. The Rickettsial bodies observed were smaller and less regular than those in trachoma. (3 references.)

Chas. A. Bahn.

Murray, J. O. **Stevens-Johnson syndrome, report of two cases.** *Lancet*, 1947, v. 1, March 15, pp. 328.

The author reported two cases of Stevens-Johnson syndrome, one with only mild conjunctivitis, and the second with profuse purulent conjunctival discharge, but without corneal inflammation. Both patients ran a comparatively mild course and cleared completely. This was interesting, as the author points out, because in many of the previously reported cases serious ocular complications have occurred, including blindness. O. H. Ellis.

Nellen, Maurice. **Stevens-Johnson syndrome.** *Lancet*, 1947, v. 1, March 15, pp. 326-327.

A case of Stevens-Johnson syndrome with severe constitutional symptoms and eruptions affecting the skin and mucosa is reported. Accompanying the purulent conjunctivitis, granular swellings were present in the upper quadrants of the bulbar conjunctiva. These were possibly the remains of subsiding vesicles, but cleared without complications. Patients with similar findings have been reported elsewhere as "erythema exudativum multiforme plurifacialis," and under other headings.

O. H. Ellis.

Thygeson, P. **Clinical signs of diagnostic importance in conjunctivitis.** *Jour. Amer. Med. Assoc.*, 1947, v. 133, Feb. 15, pp. 437-441.

There are a number of clinical signs, both gross and biomicroscopic, which are of diagnostic importance in conjunctivitis.

Changes in the regional lymph nodes, the lid margins, the limbus and cornea are of almost equal diagnostic importance with those occurring in the conjunctiva itself. By clinical examination alone it is possible to identify many of the various etiologic types of conjunctivitis. When these clinical observations are correlated with cytologic and bacteriologic studies, the cause can be determined in a high percentage of cases.

CORNEA AND SCLERA

Almeida Rebouças, José de. **Corneal ulcer from varicella.** *Rev. Brasileira de Oft.*, 1946, v. 5, Dec., pp. 105-114.

The author records five cases of corneal ulcer from varicella, in which the clinical course differed from that ordinarily described for cases in other parts of the world. Previous case

records have mentioned mild photophobia, mild pericorneal injection, rapid cicatrization, ready healing under ordinary therapy, and a delicate final scar interfering little with visual acuity. The author's patients had intense photophobia, intense pericorneal injection, cicatrization requiring from two to four months, resistance to all therapeutic measures, and a subsequent dense leucoma with considerable reduction of visual acuity. W. H. Crisp.

Casari, G. F. **Acute pemphigoid of the cornea.** *Rassegna Ital., d'Ottal.*, 1946, v. 15. Nov.-Dec., pp. 511-517.

The case described occurred in an 11-year-old girl, ill with polyarticular rheumatism and endocarditis. Small hemorrhagic spots appeared first upon the face and then became general. Even the palms of the hands showed vesicles filled with serohemorrhagic fluid and the oral mucosa was affected. On the twenty-eighth day the left cornea became completely opaque and soon a large central ulcer with purulent secretion developed. There was no glandular enlargement. Smears and culture showed extracellular cocci in clusters, with 2 percent of eosinophiles. Healing eventually took place but vision was reduced to light perception. The term pemphigoid is applied to this condition to correspond to the more recent classification of bullous cutaneous eruptions.

Eugene M. Blake.

Figueiredo, N. P. de. **Opacification of the cornea from obstetric traumatism.** *Rev. Brasileira de Oft.*, 1946, v. 5, Dec., pp. 115-119.

After forceps delivery, in addition to local swelling and hemorrhages, the left cornea was completely opaque. The condition rapidly improved, and after 61 days all that remained of the dis-

turbance were some striae. The condition has been attributed to rupture of Descemet's membrane, with secondary swelling. W. H. Crisp.

Nectoux, R. **Keratitis in epidemic parotitis.** *Ann. d'Ocul.*, 1946, v. 179, Nov., pp. 597-600.

Among the rarer complications of mumps is keratitis. Less than ten cases have apparently been reported in the world literature. During an attack of epidemic parotitis a 47-year-old woman had a transient corneal edema in one eye with slight ciliary injection that lasted about one month. There were numerous folds of Descemet's membrane, the cornea was temporarily hypesthetic and numerous erosions existed on the anterior surface. Complete healing occurred within 30 days. (5 references.) Chas. A. Bahn.

Pickrell, K. L. **Tattooing of corneal scars with insoluble pigments.** *Plastic and Reconstructive Surg.*, 1947, v. 2, Jan., pp. 44-59.

Knapp first introduced this technique in 1925. Pischel, in 1930, spoke of its failure and only one article has been written on the subject since then.

The effect of 2-percent and 5-percent preparations of iron, gold, silver, and platinum on the intact and the de-epithelized cornea of rabbits was noted. Corneal scars were first produced in albino rabbits by instilling 10-percent solution of formalin into their eyes. The scars were first tattooed with a single pigment. There was no change even after several months. Injections of colors for detailed shades were next made seven to ten days after the first or basic color injection. The final desired color could not be obtained by mixing the necessary pigments and using this mixture at one time.

Three cases of tattooing in man are presented; the patients were white females aged 7, 18, and 20 years respectively. Three tattooings about two weeks apart were performed in the child; the others received four, at five to six day intervals. Slight discomfort from photophobia was the main complaint following the treatments. After 12 to 18 months there has been no fading or dispersion of pigment. In these cases vision seemed improved by a reduction in the photophobia when light from troublesome intraocular beams were absorbed in the cornea.

Pinticart de W., E. Tuberculosis, tuberculoses, tuberculous toxemias, and tuberculin therapy. *Rev. Brasileira de Oft.*, 1947, v. 5, March, pp. 159-166.

These subjects are very briefly considered by the author, whose paper is mainly devoted to the report of a personal case. A woman of 29 years, who had three living children and had lost one from an intestinal affection, was again in an early stage of pregnancy. An ocular inflammation was attributed to a blow on the eyebrow two weeks previously. The inflammation, which was a keratitis, and which had been noted on the hospital record at the eighth month of a previous pregnancy, appeared to have become aggravated by the present pregnancy. Ocular pain became less after artificial interruption of the pregnancy; but a month later a small tubercle of the iris was found although the eye was no longer congested. Sterilization was recommended.

Volero, M. Neuroparalytic keratitis and heterochromia in syringomyelia. *Rassegna Ital. d'Ottal.*, 1942, v. 11, Nov.-Dec., p. 435.

Volero describes a case of neuroparalytic keratitis and heterochromia in a patient with the bulbar type of syringomyelia. He concludes that the trophic changes which develop in the cornea are not due, as is commonly held, to a lack of trophic impulses, nor to the presence of abnormal irritative stimuli, but to the loss of the normal control exercised by antidromic impulses resulting from faulty cellular exchange. The keratitis is due directly to the syringomyelia and not to the loss of lacrymal secretion.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Bárány, E. H. The influence of intraocular pressure on the rate of drainage of aqueous humour. Stabilization of intraocular pressure or of aqueous flow. *Brit. Jour. Ophth.*, 1947, v. 31, March, pp. 160-176.

These experiments were performed to investigate the existence of a mechanism for regulating intraocular tension by slowing or speeding the rate of aqueous flow. Such a mechanism is assumed to exist. All previous experiments have actually been unphysiological in that in all some trauma was inflicted upon the eye. Bárány maintained a completely normal physiologic relationship and arrived at contrary conclusions. The changes in tension were accomplished by pressure on the unilateral common carotid artery. The rate of aqueous flow was determined by the use of a radio-active sodium isotope as a tracer substance. It was shown that the sodium concentration remained approximately the same in the two eyes though only one underwent pressure changes as great as 20 percent.

Cyukrasz, Ida. A case of bilateral genuine iris-atrophy. *Brit. Jour. Ophth.*, 1947, v. 31, March, pp. 176-179.

A 24-year-old woman complained of blindness in one eye and poor vision in the other. The tension in each eye was 56 mm. Hg. In each eye the iris consisted mostly of atrophic strands of varying width, some of which adhered to the lens. Cornea, lens, vitreous and retina were normal and both discs showed deep glaucomatous cupping. No evidence of previous inflammation could be found and the diagnosis of genuine iris-atrophy was made. It probably arose as a regression in the pupillary evolution in the fourth month of prenatal life. Cyclodialysis in the right eye was followed by normal tension.

Morris Kaplan.

Francois, J. Heterochromia iridis of Fuchs. *Ann. d'Ocul.*, 1946, v. 179, Nov., pp. 559-576.

Six cases of heterochromia iridis are presented to illustrate the different stages and types of this condition. Diminishing density of the iris stroma with subsequent atrophy and pigment absorption and dispersion especially in the posterior portion constitute the principal pathologic feature. Associated are noninflammatory corneal precipitates, posterior cortical lens opacities and imbalance of the sympathetic nervous system, usually of the parietic type. Among the rarer complications are glaucoma, retinal detachment, and vitreous degeneration. The symptoms usually begin about the age of 20 years. Usually there is ciliary injection and synechias are completely absent. The principal explanatory theories postulate inflammation, sympathetic nervous system degeneration, and dysraphic degeneration. No single theory apparently explains all cases. Fuch's heterochromia iridis is apparently a degenerative genetic syndrome, involving defective structure of the iris and lens with partial or complete lack of normal tissue repair. Another part of the syndrome is a degeneration of the autonomic nervous system especially involving the cervical sympathetic portion.

Hartmann, E., and Braun-Vallon, S. Ocular toxoplasmosis. *Ann. d'Ocul.*, 1946, v. 179, Oct., pp. 524-530.

Bilateral disseminated chorioretinitis involving the perimacular region suggests toxoplasmosis, particularly in infants. The parasite is 4 to 6 μ by 2 to 3 μ pear shaped, easily inoculated into guinea pigs and mice, and is frequently found in rodents and birds. The exact mechanism of infection, especially of infants, is not known.

In infants the infective process is essentially an encephalomyelitis which

is frequently fatal. Mothers usually have antibodies in their blood but are free from symptoms. In older children and adolescents the process is less acute with fewer constitutional symptoms. In adults the liver and spleen are frequently involved in the general infection, which is usually less severe than in the young and which clinically resembles Rickettsia infections, especially typhus fever. The basic lesion is a small perivascular granuloma in which lymphocytes, epithelioid cells and occasionally eosinophiles are present. The infection reaches the primarily involved choriocapillaris and the first neurone of the retina through the blood stream. The chorioretinal lesions may be confused with those of hereditary lues, small pox, measles, tuberculosis, lead poisoning, and congenital coloboma. The location of the ocular lesions, the absence of marked proliferative changes, and the bilateral occurrence are characteristic. The extraocular symptoms, positive complement-fixation test in the acute stage, positive rabbit and mouse inoculation, and calcium deposits in the cerebellum further facilitate differential diagnosis. Jona, S., and Baue, A. **Considerations on an atypical case of Harada's Disease.** *Riv. Oto-Neuro-Oft.*, 1946, v. 21, May-Aug., pp. 168-182.

A woman, 43 years of age was suddenly taken sick with violent headache and high fever. After a few days, there was loss of vision of the right eye. Ophthalmoscopic examination revealed a red reflex from the fundus and a retinal detachment below. Her spine was rigid, and the spinal fluid contained lymphocytes. There was also a reddish maculo-papular eruption on the skin and vesicular lesions of the lips and

mouth. The general symptoms abated in a short time but seclusion of the pupil persisted. The herpetic lesions of the mouth suggest that the disease was caused by a herpetic virus which was uveotropic. (Bibliography.)

Laval, Joseph. **Hemorrhage in sarcoma of the choroid.** *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 607-609. (4 figures.)

Martin-Jones, J. D., **Uveal Sarcomata.** *Brit. Jour. Ophth.*, 1946, Monograph Supplement 11.

This monograph brings our knowledge and the literature of this large subject up to date. Two hundred and sixty-three cases were completely investigated. Heredity was a possible factor in only two instances, and although trauma was often mentioned, it was a very questionable causative agent. Previous choroidal hemorrhages and old pigmentary changes in the fundus were, in some cases, thought to be predisposing factors. The condition appeared equally in the two sexes and at any age. The average age was in the sixth decade. Most of the eyes were nearly blind at first examination; however five had 6/6 vision.

The average duration of symptoms was 19 months, and differential diagnosis was rarely difficult when the fundus was clearly seen. In no case was a hole or tear of the retina seen with sarcoma of the choroid, and detachments with increased intraocular pressure (present in 50 percent of cases) were usually neoplastic in origin. The glaucoma may have been caused by the formation of a plasmod type of fluid, as well as the usual mechanical blockage.

The choroidal type is the most com-

mon intraocular sarcoma and most frequently arises in the posterior pole. Bilateral or multiple choroidal sarcomas are extremely rare. The spindle celled growths are the most common, those composed of epithelioid cells alone are rare, and the mixed cell type is the most malignant.

The author presents a comprehensive discussion of the origin of these tumors, and conclusively shows them to be mesoblastic in origin.

More than one half of the patients died within ten years after operation. The patient who survives for ten years is probably cured. Malignant cells in the emissaria are not necessarily of bad prognostic import but extraocular involvement is. There was no evidence to show that intracranial extension of the growth occurred when the optic nerve was invaded by sarcoma cells. Reticulum staining on a group of specimens confirmed the work of Callender and Wilder as to the prognostic importance of the content of the reticulin fibers in the tumor.

Extraocular extension of the growth is the exception and not the rule, and early enucleation is the treatment of choice. Exenteration of the orbit does not increase the chance of survival and radium or X-rays probably are as effective.

Sarcoma of the iris is rare. It arises from proliferation of the stroma cells, usually on the lower half of the iris and also should be removed early by enucleation. (20 illustrations and photomicrographs.)

Matteucci, Pellegrino. Sympathetic innervation of the uvea and its neurovegetative regulation. *Rassegna Ital. d'Ottal.*, 1946, v. 15, Nov.-Dec., pp. 484-498.

Mawas demonstrated a neurovega-

tive regulatory system in the retina and along the course of its vessels. This system consists of ganglion cells and microganglia of a sympathetic nature. This is contrary to the usual opinion that the retinal arteries are not under direct influence of vasomotor nerves. Matteucci conducted experiments upon rabbits and disagrees with Mawas and Magitot. His experiments seemed to show that the autonomic regulation of the uveal vessels is a sinus reflex, which regulates the intracranial and general arterial pressure and appears to act in a direct manner through the medullary bulb upon the caliber of the uveal vessels and the ocular tension. The sympathetico-adrenal and parasympathetico-colinergic systems are represented only by way of transmission of these reflexes.

The vacillations of general arterial pressure do not seem to act in a mechanical sense upon the caliber of the uveal vessels. Considerable difference of opinion exists among physiologists, anatomists, and others working upon the problem of the nervous control and uveal vessels, general and vascular arterial pressure and in intraocular tension, and knowledge in this field is in a state of flux. (2 figures.)

Pinticart de W., E. Tuberculosis, tuberculoses, tuberculous toxemias, and tuberculin therapy. *Rev. Brasileira de Oft.*, 1947, v. 5, March, pp. 159-166. (See Section 6, Cornea and sclera.)

Roper-Hall, M. J. Research in Zurich. *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 223-228.

The author presents a summary of the work done at Zurich on the pathological changes in the aqueous humor and the blood-aqueous barrier. Over

1900 anterior chamber punctures were done on normal and diseased eyes. The cells, which are increased in inflammation, originate in the blood and neighboring tissues. The predominant role of the reticuloendothelial system in a great number of cases of chronic uveitis was noted. Albumin was increased in proportion to the number of cells, and in chronic inflammations there was a dissociation found between the albumins and the cells, comparable to that observed in the pathologic cerebrospinal fluid. Cultures were rarely positive even with strongly positive smears, and tubercle bacilli were found in only one case. Organisms found in the anterior chamber in keratitis and anterior uveitis were of etiologic significance.

The permeability of the blood-aqueous wall was studied with the intravenous fluorescein method. Trauma, uveitis, and most general diseases show an increased permeability; however the findings in glaucoma varied. It was found that the fluorescein test showed more minute changes in the permeability of the wall than the Tyndall effect.

Rubino, A., and Rosselli del Turco, L. A case of uveitis with vitiligo; study of Vogt-Koyanagi's disease. *Riv. di Oftalm.*, 1946, v. 1, Sept.-Oct., pp. 553-571.

A 15-year-old girl had been suffering from bilateral iridocyclitis since the age of 9 years. At the age of 8, she had a tracheobronchial adenopathy accompanied by loss of weight and one year later pulmonitis was diagnosed. Two years after the eyes became involved, the skin showed patches of depigmentation. The anterior part of the uvea was only slightly involved; the vitreous of both eyes contained diffuse opacities consisting of powderlike pigment par-

ticles. The disease recurred at irregular intervals, and reduced the visual acuity of the right eye to 3/50, and of the left to 3/10. The authors concluded that the disease was a transition between Vogt-Koyanagi's and Harada's disease. A virus, similar to, or identical with, herpes virus, could produce the vitiligo by invading the terminal branches of the cutaneous nerves and also might produce the ocular lesions. It could likewise be assumed that an allergy of the skin was associated with a hyperergy of the eyes or that pigment-dissolving antibodies might have been formed in the uvea. GLAUCOMA AND OCULAR TENSION

Bárány, E. The influence of local arterial pressure on aqueous humor and intraocular pressure. An experimental study of the mechanisms maintaining intraocular pressure. *Acta Ophth.*, 1946, v. 24, pt. 4, pp. 337-387.

This is a detailed report of a comprehensive investigation on rabbits, in an effort to demonstrate the presence of hemostatic reflexes which control the intraocular pressure. The tension of the eyes of rabbits with a van Leersum carotid loop was measured with a tonometer under local anesthesia, from a few seconds to three hours after clamping the loop. The difference in the pressure of the two ophthalmic arteries caused by the unilateral carotid occlusion was estimated from the difference in the peripheral pressure between the

two halves of the head; this was determined by compression of the two central arteries of the ear of the moderately heated unanesthetized animal. That a direct correlation exists between the two pressures was shown by a direct determination of the pressures in the ophthalmic arteries. The absolute difference between the ophthalmic artery pressures is greater than the difference between the ear artery pressures, but the ratios are approximately equal. The graphic data show that on closure of the carotid the mean blood pressure in the ear artery drops to one third of the starting level, but recovers rapidly during the following few minutes, and after 10 minutes keeps a constant level of about one half of the pressure on the other side. This level is maintained for at least one hour. At the same time the intraocular pressure gradually drops by about 4 mm. Hg during the first two seconds, and about $\frac{1}{2}$ mm. during each subsequent second. During the following few minutes there is a partial recovery. On the average the intraocular pressure drops about 3.5 mm. Hg within three minutes after the carotid is closed. There is no sudden change of the curve to indicate the existence of a reflex that quickly regulates intraocular pressure. On the contrary, the extent and the rate of recovery of the intraocular pressure closely corresponds to the recovery of blood pressure. During the hours following carotid closure the intraocular pressure remains at a constant level of about 3 to 3.5 mm. Hg below that of the control eye. There is no indication of a regulating reflex of slow action.

Bozzoli, Alessandro. Perforating diathermy coagulation of the corneoscleral limbus in ocular hypertension. *Riv. di*

Oftalm., 1946, v. 1, Sept.-Oct., pp. 631-633.

This preliminary note reports a new procedure used in ten cases of ocular hypertension. After retrobulbar anesthesia, a small conjunctival pocket is undermined beginning $1\frac{1}{2}$ cm. above the limbus. Every bleeding vessel is electrically coagulated to avoid hemorrhage. The electric needle is used to penetrate the limbus in the same direction as one would enter with a keratome to perform a paracentesis. As soon as the needle enters the chamber (amperage not indicated) aqueous humor will escape and a few bubbles will form in the chamber. A peripheral iridectomy can be performed with the needle or can be added separately. The postoperative course was uncomplicated and the intraocular pressure remained normal for many months. The advantages of the operation are its simplicity, cleanliness, and absence of hemorrhage. No lens opacities were observed.

K. W. Ascher.

Cristini, Giuseppe. Clinical considerations on the action and effects of X-ray therapy on spinal sympathetic centers and superior cervical ganglion of normal and glaucomatous eye. *Riv. Oto-Neuro-Oft.*, 1946, v. 21, May-Aug., pp. 199-225.

The author tested the effect of Roentgen irradiation of the spinal cord and the superior cervical ganglion in 15 patients some of whom had normal eyes others latent or well developed glaucoma. Eleven of the patients were men and four women and they ranged in age from 32 to 73 years. The results are given in tabular form. In glaucoma the sympathetic vegetative regulation is depressed. The writer emphasizes the importance of this new therapeutic procedure to reduce the increased intra-

ocular tension temporarily. (Bibliography.) Melchiorre Lombardo.

Louhela, T., and Teräskeli, H. On the results of different glaucoma operations. *Acta Ophth.*, 1946, v. 24, pt. 1, pp. 27-43.

A brief review of the Scandinavian literature on antiglaucomatous operations is given, and an analysis of the results of 520 operations on 474 eyes is made. This is the material of the Helsinki Hospital for the years 1930 to 1942. The data are tabulated. In acute glaucoma iridectomy is the procedure of choice. A comparison between the results of cyclodialysis and iridencleisis takes into account the effectiveness of the procedure, and the complications incident to it. Of the two procedures cyclodialysis has proved more effective in reducing tension. The most feared complication of antiglaucomatous operations, which is cataract, does not occur immediately in cyclodialysis. It occurred once in 206 cases and was the result of faulty technic. In iridencleisis this complication does occur. If the time of observation is sufficiently long, however, cataract is encountered with about equal frequency after both operations. Impairment of the visual function, in the absence of cataract, is more frequent following cyclodialysis, and the end results are therefore slightly better after iridencleisis. It is difficult to determine to what extent these degenerative changes are due to the disease itself, and to what extent to surgery. The authors suggest that perhaps the sensitive uvea is subjected to more damage in cyclodialysis than in iridencleisis. (6 tables.) Ray K. Daily.

Sjögren, Henrik. A study of pseudoglaucoma. *Acta Ophth.*, 1946, v. 24, pt. 3, 239-294.

This term is applied by Thiel to glaucoma without increased ocular tension. A comprehensive review of the literature, and brief reports of nine cases of glaucoma without hypertension show that every conceivable combination with and transition to glaucoma have been described. Glaucoma without hypertension can pass over into hypertension and vice versa. Glaucoma can be present without hypertension in one eye, and with it in the other; in unilateral glaucoma the tension may be higher than in the normal eye without exceeding the normal limits or may be equal and normal in both eyes, or may even be lower in the diseased eye. In unilateral glaucoma the tension may rise in both eyes, and in bilateral glaucoma the tension may rise in one eye only; occasional rises of tension may occur in pseudoglaucoma. Acute inflammatory phenomena may develop without increase in tension, or with a slight rise that does not exceed the physiologic limits. Eyes with normal tension may exhibit occasional rises during the day, or in response to provocation. The disease may be familial, or one member of the family may have glaucoma with hypertension, and another without. After surgery, glaucoma can progress as glaucoma without tension. The pathologic changes and the functional disturbances are the same in glaucoma with and without hypertension. The pathologic picture is similar to that in cerebral atrophy; glaucoma and the brain changes may occur simultaneously in the same person. The depth of the excavation of the optic nerve has no relation to the height of the pressure and it is frequently deeper in glaucoma without tension; a high tension may exist a long time without the occurrence of excavation of the

disk. It is suggested that glaucoma with and without hypertension are the same disease, and that the term pseudo-glaucoma be reserved for congenital anomalies or pressure atrophies simulating glaucomatous excavation. The author agrees with those who hold that the basis of glaucoma is a circulatory disturbance independent of intraocular pressure. The disturbance of vascular function may produce glaucoma with hypertension, glaucoma without hypertension, and cerebral atrophy. If the disturbance involves the anterior part of the eye the result is an anterior glaucoma with hypertension; if it is located in the posterior portion of the eyeball the clinical manifestation is posterior glaucoma without hypertension; if it is located in the brain it leads to cerebral atrophy. The reported cases show that these processes may occur singly or in combination. (33 visual fields and tension curves.) Ray K. Daily.

Weekers, L., and Weekers, R. A new contribution to nonperforating cyclodiathermy in the various forms of glaucoma. *Acta Ophth.*, 1946, v. 24, pt. 1, pp. 1-24.

In this exhaustive presentation the authors review the history of the application of cyclodiathermy for glaucoma, and the technic is described. Application of the electrode over the conjunctiva results in conjunctival burns somewhat larger than the electrode, at the bottom of which one sees the apparently uninjured sclera. A detailed analysis of 76 cases of various types of glaucoma thus treated shows the effect of the procedure on the eye. Histologic sections of enucleated eyes shows that the dominating process after cyclodiathermy is an enormous vasodilatation in the uvea, followed by exudation.

Four months later an eye showed a slow cicatricial process with atrophic areas in the ciliary body. Cyclodiathermy is believed to result in a change in the equilibrium between the production and resorption of fluid, in the eye, in favor of greater resorption. The hypotonizing effect of cyclodiathermy is constant and pronounced. The operation is indicated in chronic glaucoma in which other operations have failed, and it is the operation of choice in absolute glaucoma. It is effective in the various types of secondary glaucoma. In acute glaucoma its hypotensive effect is marked but transitory.

CRYSTALLINE LENS

Arruga, H. Mishaps and complications in the cataract operation. *Ophth. Ibero Amer.*, 1946, v. 7, no. 4, pp. 275-280.

The author deals with the various difficulties under the following headings: blepharospasm, small cornea, shallow anterior chamber, friable conjunctiva, emptying of the anterior chamber, hemorrhage into the anterior chamber, ocular hypertension, vitreous in the anterior chamber, anterior synechia, posterior synechia, intumescent cataract, resistant zonula, rupture of the zonula, escape of vitreous, expulsive hemorrhage. W. H. Crisp.

Di Ferdinando, R. **Etiologic relationship between juvenile cataract and war conditions.** *Riv. di Oftalm.*, 1946, v. 1, Sept.-Oct., pp. 617-630.

The eyes of six soldiers with bilateral lens opacities are described. Three had posterior subcapsular opacities, three had punctate opacities of the coronary type. Psychic trauma, vitamin deficiency, and neuro-humoro-hormonal imbalance may have been the cause of the opacities. (4 figures, bibliography.)
K. W. Ascher.

Huggert, A. **The thickness of the cortex of the crystalline lens in different ages.** *Acta Ophth.*, 1946, v. 24, pt. 1, pp. 43-62.

The article includes a comprehensive review of the literature, and a report of original investigations on 303 experimental subjects in an attempt to measure the absolute axial thickness of the cortex of the lens at different ages. The method of using Lindstedt's apparatus with slit-lamp illumination, and the subsequent calculations are described in detail. The distances measured were from the surface of the cornea to the anterior surface of the lens; to the anterior surface of the adult nucleus; to the posterior lens pole; and to the posterior surface of the adult nucleus. The data are reported graphically. The thickness of the anterior lens cortex is relatively similar at all ages, and increases by about 0.007 mm. per annum; the calculated thickness of the posterior cortex is probably the same. The size of the adult nucleus appears to be unchanged throughout the years.

RETINA AND VITREOUS

Alvaro, M. E. **Use of roentgen rays in treatment of retinal disorders characterized by new formation of vessels—Eales disease, arteritis, periphlebitis and endophlebitis, proliferating retinitis.** *Rev. Brasileira de Oft.*, 1946, v. 5, Dec., pp. 71-87.

The author discusses at some length the probable effect of X rays upon the capillary circulation, as studied by various writers on radiology. The hematopoietic organs are extremely sensitive to X rays. Moderate doses cause immediate dilatation of the capillaries. The action of the rays may also include a greater permeability of the endothelium. Conflicting results stated by different authors arise from wide variation in the dosage employed, but there is more or less unanimity in the opinion that the dosage should be very small, always less than one skin erythema dose, and in most cases not more than one half of this dose, generally administered in fractions. According to Alvaro, the hard rays should be employed. Clinical experience over several decades appears to justify the employment of X rays in the treatment of the conditions mentioned in the title. (Bibliography.)
W. H. Crisp.

Arruda, Jonas de, and Sebas, S. R. **Degenerative macular disorders.** *Rev. Brasileira de Oft.*, 1947, v. 5, March, pp. 135-155.

A study of the literature leads the author to suggest that these lesions be classified into two main groups, acquired and hereditary, with six subdivisions: (1) acquired; central recurring retinosis, exudative macular retinosis, and cystoid degeneration of the macula; (2) hereditary; hereditary degeneration of the macula, colloid hereditary degeneration of the macula, and macular degeneration in familial amaurotic idiocy. (5 illustrations reproduced from other authors; short bibliography.)

W. H. Crisp.

Drualt, A., and Drualt, S. **Anterior limits of the retina.** *Ann. d'Ocul.*, 1946, v. 179, Oct., pp. 531-539.

The anterior attachment of the retina is not concentric with the corneal limbus, but slightly more forward on the nasal side, which facilitates the larger temporal visual field. Nasally the retina extends to within 8 mm. of the corneal limbus and temporally to about 10 or 12 mm. Retinal function extends forward to approximately the level of the ocular nodal point which corresponds with the center of the lens. This is of importance in the surgery of retinal detachment. In section, the retina is approximately two thirds of a circle, and is attached firmly only at the ora serrata and the optic nerve. Peripherally the proportion of rods to cones is approximately 20 to 1. (17 references.)

Falls, H. F. **Inheritance of retinoblastoma, two families supplying evidence.** *Jour. Amer. Med. Assoc.*, 1947, v. 133, Jan. 18, pp. 171-174.

Two pedigrees are presented to support the contention that retinoblastoma is a hereditary form of neoplasia. In one family bilateral retinoblastoma occurred in each of a pair of "single

cord" female identical twins, the third such pair in the literature. The tumors were noted at the age of six months, and both infants quickly died. In the other family the mother of a child with retinoblastoma had an enucleation of her left eye at the age of 3½ years because of retinoblastoma. Five of the nine siblings of the mother's generation had diagnoses of retinoblastoma, and two of these survived to reach child-bearing age. This pedigree adds to the list of reported observations of the "vertical transmission" of the neoplasm. The author strongly feels that parents of a child who develops retinoblastoma should have no more children, and that any survivor of enucleation for retinoblastoma should be sterilized. (2 figures, abstract of discussion.)

Gordon, D. M. **The treatment of retinitis pigmentosa with special reference to the Filatov method.** *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 565-579. (1 table, 39 references.)

Gördüren, Süreyya. **A Grönblad-Strandberg syndrome.** *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 228-232.

The author discusses the literature and presents an interesting case of Grönblad-Strandberg syndrome, with the two components of the disease, angioid streaks and pseudo-xanthoma elasticum, clearly demonstrated. Angioid streaks, which are due to the widespread degeneration of elastic tissue were present in both eyes. A large yellow raised mass was present in the posterior pole of one eye. The skin of the neck and abdomen had a parchment-like appearance with raised yellow streaks. Microscopic examination of the skin in biopsy, showed degeneration of the elastic elements. (7 illustrations.)

O. H. Ellis.

Holm, Stig. Macular proliferation (pseudotumor) and closely related pictures of disease (retinitis circinata, Coats's disease, etc.) *Acta Ophth.*, 1941, Supplement 18.

The cases of macular proliferation and borderline cases, and the reported cases of retinitis circinata that have been examined histologically are reviewed. A clinical, ophthalmologic, and histologic description is given of a case of macular proliferation in the form of a pseudotumor, which presented the picture of retinitis circinata, in a woman 82 years of age. The pseudotumor was twice as large as the largest pseudotumor that has been reported. A case of a subretinal hemorrhage with macular proliferation is also reported. An analysis of this material suggests that an activation of the pigment epithelium layer of the retina is the primary cause of the development of pseudotumor. This activation may have induced the intense proliferation of pigment cells. It seems probable that the pigmented epithelium is responsible for the new formation of connective tissue. The ganglion cell layer was found intact, which accounts for the absence of changes in the optic disc. The histologic basis of retinitis circinata is not definite; the ophthalmoscopic picture of retinitis circinata may be caused by intraretinal changes, by subretinal accumulation of fluid, and by newly formed subretinal connective tissue and subretinal degenerated pigment epithelium. The review of the literature shows that ophthalmoscopically and histologically the picture of macular proliferation may also be seen in angiomatosis of the retina, in the macular changes in angioid streaks, in exudative macular juvenile retinitis, and in chronic central retinochoroiditis. The

soft membranes of the eye seem to react in the same manner to different pathologic agents. The differential diagnosis from a malignant tumor is very difficult, and transillumination does not give definite data. (12 photomicrographs, 6 fundus photographs.)

Kaminskaya-Pavlova; Z. Pathogenesis of fundus changes in skull injuries. *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 613-615.

Longhena, Louisa. Gangliectomy for treatment of retinosis pigmentosa. *Riv. Oto-Neuro-Oft.*, 1943, v. 3, May-June, pp. 135-153.

Resection of the stellate ganglion of the sympathetic was performed in seven patients suffering from retinosis pigmentosa. In one the operation was performed bilaterally. In three patients, no improvement of the visual function was observed and in one, a slight improvement occurred; In three other patients, the visual acuity was increased distinctly after the operation, and in two of them the visual fields were less constricted after the operation. Dark adaptation also was improved in some of the patients. Early operation is advocated to preserve what is left from the slowly degenerating retinal tissue. After the operation, ptosis and miosis become obvious and persist for an indefinite period; conjunctival hyperemia is always present; the retinal vessels are dilated for months in some patients, but in others the vascular diameter does not seem to be markedly greater in the eye of the operated side. Moderate headaches, pain in the neck and in the shoulder were observed occasionally; in two patients, a permanent hoarseness followed the operation.

K. W. Ascher.

Schneider, R. W., McCullagh, E. P., Ruedemann, A. D., Kennedy, R. J., and Lewis, L. A. Hemorrhagic diabetic retinitis; a method of treatment based on the elevation of plasma albumin by diet. *Cleveland Clin. Quart.*, 1947, v. 14, April, pp. 76-80.

In patients with diabetic retinitis, plasma proteins are normal or slightly reduced in quantity and there is a relative decrease of albumin and increase of beta globulin. Plasma albumin levels in this group are not readily corrected, and 100 to 200 grams of protein per day for many months are necessary to decrease the tendency to exudation and hemorrhage. Of 16 patients observed for two to three and a half years the plasma protein pattern was corrected and the recurrent hemorrhages disappeared in six, and were decreased in one.

Irwin E. Gaynon.

Paez Allende, F. A case of arachnodactyly, or Marfan's disease, with subluxation of both lenses and high myopia. *Anales Argentinos de Oft.*, 1946, v. 7, July-Aug.-Sept., pp. 81-85.

This typical syndrome consists of elongated stature, long extremities with fine, elongated, spidery fingers and toes, muscular hypotony, easy dislocation of body joints, luxation or subluxation of the lenses, myopia, and various other secondary derangements, physical and mental. The etiology and pathogenesis cover the fields of toxic states, muscular dystrophy, atavisms, primary hormonal disease, and disturbances of the nervous system. In the presentation of the author's case, a seven-year-old girl, the following features were of diagnostic importance: height greater than normal for her age, asthenia, melancholy facies, long, tapering fingers, left partial heterochromia iridis, bilateral

iridodonesis, bilateral nasal subluxation of the lenses, and over twenty diopters of myopia. (Bibliography.)

Edward Saskin.

Weinstein, P., and Forgács, J. Circulatory studies of the fundus of the eye. *Brit. Jour. Opth.*, 1947, v. 31, April, pp. 238-242.

Patients with spontaneous venous pulsation of the blood vessels of the fundus have a better retinal circulation and have 50 percent less retinal complications than persons without pulsation. In patients with pulsation the pressure drop from the arterial to the venous circulation is greater; without pulsation the arterial pressure is established at a higher level which signifies capillary obstruction. Spontaneous venous pulsation disappears with the reduction of intraocular tension by massage of the globe. O. H. Ellis.

EYEBALL AND ORBIT

Azzolini, Umberto. Orbital angioma. *Riv. Oto-Neuro-Oft.*, 1943, v. 3, May-June, pp. 184-198.

A 42-year-old woman had suffered from headaches for years, and noticed protrusion of her left eyeball and increasing diplopia for the past two years. An unreducible proptosis was found and the external rectus muscle of the left eye was paretic. Radiologically an opaque region was found in the left orbit, and a Kroenlein operation was performed, with the tentative diagnosis of meningioma. A cavernous angioma was found. The postoperative course was complicated by a hemorrhage into the tip of the orbit, which slowly was reabsorbed. (7 figures.)

K. W. Ascher.

Babel, J. **Orbital chronic inflammation and pseudo-tumors.** *Ann. d'Ocul.*, 1946, v. 179, Oct., pp. 540-550.

Many years ago Birch-Hirschfeld divided slow space-taking orbital lesions with slight or no inflammatory reaction into three groups: 1. those which disappeared after nonspecific therapy; 2. those which contain diffuse chronic inflammatory tissue; 3. those characterized by the formation of lymphoid and degenerative vascular changes.

A 62-year-old woman had a slight recurrent inflammation of the lids and orbit with exophthalmos during a period of 20 years. Ocular movements were limited in all directions. Upon exploration, a mass of inflammatory tissue was removed from the orbit which consisted essentially of dense cicatricial tissue. Orbital radiography showed erosion and diffuse osteoporosis of the superior external border of the left orbit that suggested a neighboring inflammatory process. This case conformed to Birch-Hirschfeld's class 2.

A 22-year-old woman had a slight ptosis, and a hard tumor that involved the upper external angle of the orbit. Otherwise both eyes were normal and had normal vision. A rounded mass was removed which included a part of the lacrimal gland. The pseudotumor was considered secondary to dental infection.

The third patient was a woman, 67 years of age, who had developed an almond-sized painless mass in the right orbit near the superior external angle during the previous year. Otherwise both eyes were normal except for a senile macular degeneration. Under the orbitotarsal fascia an extremely friable and unencapsulated tumor was removed. This consisted largely of lacri-

mal gland with chronic inflammatory changes. (17 references.)

Chas. A. Bahn.

Bey, Handousa. **Some observations on the symptomatology and diagnosis of cases of proptosis.** *Brit. Jour. Opth.*, 1947, v. 31, March, pp. 155-160.

Bey reports his experience with proptoses. The largest number, 31, originated from intraorbital lesions such as inflammation, cysts, and neoplasms. A few were secondary to diseases of the paranasal sinuses, and a small group were caused by traumatic, inflammatory, and neoplastic changes in the bony wall of the orbital cavity.

Morris Kaplan.

Delsores, Jose. **Orbital phlegmon treated with sulfanilamide.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, July, pp. 673-675.

The patient was given five grams of Leuco-tiazol by mouth daily during the first four days (0.5 Gram every two hours) and four Grams daily the next three days. At the end of the eighth day the inflammation had subsided. The above dosage was sufficient to keep the blood concentration of the drug at the effective level.

J. Wesley McKinney.

Esente, Ivan. **Radiologic and histologic study of two eyeballs containing ossifications.** *Riv. di Oftalm.*, 1946, v. 1, Sept.-Oct., pp. 604-616.

Comparison of radiograms and microscopic sections of two atrophic eyes proved the value of radiologic examination for diagnostic purposes. The bony tissue was derived directly from the connective tissue. (10 pictures, bibliography.)

K. W. Ascher.

Forbes, S. B. **Exophthalmos in relation to orbital tumors; report of eight cases.** *South. Med. J.*, 1947, v. 40, March, pp. 206-213.

This is a report of eight cases of unilateral exophthalmos. In four the proptosis resulted from a primary orbital tumor, in three from a tumor outside the orbit, and in one from a prietary pseudotumor. A lipoma was not changed by irradiation, and transconjunctival surgery was done. Now there is a slight enophthalmos. A squamous cell carcinoma occurred about the left orbit and sphenoidal ridge (presumably metastatic, though the primary focus was not found), and the patient died about nine months after the eye had begun to protrude. A third patient had a pyocoele of the ethmoid which was treated surgically with success. A mucocoele of the ethmoid was similarly treated with an excellent result. The fifth patient developed exophthalmos after a second thyroidectomy. A Krönlein operation was done. The lateral and inferior muscles were very large. A pseudo-tumor receded after irradiation in fractional doses. The other two cases resulted from benign cavernous hemangiomas; in both a Krönlein operation was done, with good results. (12 photographs.)

Bennett W. Muir.

Kestenbaum, Alfred. **A new principle of relative exophthalmometry.** *Confinia Neurologica*, 1946, v. 7, no. 3-4, pp. 113-120.

While the patient is looking upward, a ruler is held horizontally in front of and parallel to the patient's face. The inferior edge of the ruler is on the same level as the lowest point of the limbus. The distance between the limbus and ruler is equal to the width of the ruler.

The observer looks over the ruler's upper edge and brings his head to a level where he sees the left inferior edge of the patient's limbus with his right eye, aligned with the upper edge of the ruler. Then he looks at the other eye without changing position. If relative enophthalmus is present, a strip of sclera will be visible above the edge of the ruler. The measurable strip of visible sclera equals the degree of relative enophthalmus. (2 figures.)

Irwin E. Gaynon.

Moreira de Andrade, Luiz. **General considerations on a case of traumatic pulsating exophthalmos.** *Rev. Brasileira de Oft.*, 1947, v. 5, March, pp. 171-178.

A youth aged 16 years received a violent blow on the head from the door of a bus in which he was riding, and was taken unconscious to the hospital. There was a fracture in the right temporo-parietal region, disclosed by X ray. Examination showed moderate exophthalmos on the right side, reduced movement of elevation of this eye, and homonymous diplopia. Both external rectus muscles were inactive, and there was a distinct Babinski reflex on the left side. Some weeks later the patient complained of intense headache and a buzzing. The conjunctival vessels were considerably disturbed, there was considerable chemosis in each eye, and exophthalmos in each eye but especially the right. Vision was right $\frac{2}{3}$, left 1. Pulsation was noticeable on palpation on each side, and a bruit was audible through the stethoscope, especially on the right side. Improvement followed ligation of the right common carotid. Vances, P., Ianou, A., and Metianu, I. Subacute staphylococcal septicemia with severe orbital maxillary symptoms cured by penicillin. *Ann. d'Ocul.*, 1946, v. 179, Oct., pp. 511-523.

A five-weeks-old infant with facial pyoderma since birth developed severe palpebral and conjunctival edema with exophthalmos, a seropurulent nasal secretion, a slight deformation of the palate and severe febrile symptoms. During the following ten days the ethmoids were curetted and the lower temporal portion of the orbit was drained. Penicillin (50,000 units) was injected into the orbital tissues. The ocular symptoms greatly improved until the eighteenth day when a recurrence began. The orbital wound was drained, penicillin (10,000 units) was immediately injected into the orbital tissues, and one half of the quantity was injected every three hours. One week later the patient was practically well. The authors believe that the lesion was the result of a staphylococcal septicemia that resulted from the facial pyoderma. Staphylococci were identified by stain-

ing and culture in the affected tissues. A constitutional predisposition (lymphatic exudative diathesis) made possible the secondary staphylococcal infection that rapidly extended into the nose, paranasal sinuses, and orbit. (51 references.)

EYELIDS AND LACRIMAL APPARATUS

D'Eramo, C. Congenital fistula of the lacrimal canal. *Anales Argentinos de Oft.*, 1946, v. 7, July-Aug.-Sept., pp. 79-80.

A five-year-old child is presented who had tearing of the left eye since birth, and a small discharging orifice about five millimeters below and internal to the inner canthus. Exploration of the orifice by irrigation showed that fluid entered the sac and appeared at the inferior nasal meatus. The author felt the fistula was congenital and he contemplated surgical extirpation. (1 radiograph.)
Edward Saskin.

Kiskadden, W. S., and McGregor, M. W. Coloboma of the eyelids. *Plastic and Reconstructive Surg.*, 1947, v. 2, Jan., pp. 60-65.

The authors present a case of congenital coloboma of the inner portion of each upper eyelid in an infant, one of unidentical twins, aged one week. Boric acid irrigations and ointment did not prevent some corneal ulcerations although thorough care was given by the infant's mother, a nurse. When the child was 2½ months of age, surgery was performed. The technique, as well as that of Falchi, Wicherkiewicz, Peer, and Hughes is described. The original corneal scarring has largely disappeared and it is believed that little permanent defect will result.

Francis M. Crage.

Landau, J. A case of congenital vertical shortness of the lids combined with tetrastichiasis. *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 219-222.

The author reviews the literature, and presents an unusual case of congenital vertical shortness of the lids. The patient also had tetrastichiasis, combined with a partial eversion of the cutaneous part of the upper lid margin. It appeared that the hair follicles of the supernumerary cilia had taken the place of the Meibomian glands, and occupied their ducts. No inflammation of the eyes had occurred. O. H. Ellis.

Harms, H. H., and Ryerson, F. L. Coloboma of optic nerve. *J. Michigan M. Soc.*, 1947, v. 46, Feb., pp. 214-215.

The authors describe a coloboma of the left optic nerve in a 51-year-old Negro woman. The findings were negative except for a four-disc-diameter excavation that is 12 diopters deep. The deepest inferior portion is blue white, and the area above is bluish pink, and has a veil. The vessels bend sharply over the inferior margin of the disc. The superior portion of the optic disc is normal. Central field studies revealed an enlarged blindspot.

Irwin E. Gaynon.

Price, H. W. Dacryostenosis. *J. Pediat.*, 1947, v. 30, March, pp. 302-305.

Of 203 infants with dacryostenosis 192 recovered with conservative therapy which consisted of irrigation of the eye with boric acid solution and pressure over the lacrimal sac. The latter is applied three times daily. With a rocking motion from above downwards at the inner canthus an attempt is made to expell the contents of the sac through the nasolacrimal duct into the nose. Irwin E. Gaynon.

Seidenari, Renato. Study of the bony part of the nasolacrimal duct and of the nasal mucous membrane surrounding the orifice of the nasolacrimal duct. *Minerva med.*, 1947, v. 1, Feb. 10, pp. 176-181.

Investigations of the nasal mucous membranes and the bony ducts of four corpses showed that dacryocystitis need not be connected with inflammatory disease of the nasal mucosa surrounding the orifice of the nasolacrimal duct. There is, however, a narrowing of the bony ducts and a more winding course than in individuals not affected by dacryocystitis. The veins of the mucous membrane of the duct form a dense network, almost an erectile tissue according to Magitot; slight nasal congestion may suffice to bring the mucous membranes of the nasolacrimal duct into apposition, which may be followed by permanent adhesions. Narrowing of the duct, as found in the specimens described, is a contributory factor. If the nasal disease recurs, another adhesion may form above and below the first one. The nasolacrimal ducts of persons without dacryocystitis are wider and less winding. (9 figures.)

K. W. Ascher.

Seidenari, Renato. Histopathology of the nasal mucous membrane adjacent to the os unguis in dacryocystitis. *Minerva med.*, 1947, v. 1, Feb. 10, pp. 181-186.

Ten cases of dacryocystitis were used for a study of the mucous membranes obtained during dacryocystotomy. Special attention was devoted to the epithelial cells, the cellular infiltration, and to the vessel walls of the region possibly responsible for the development of the dacryocystitis such as the ethmoidal anterior sinus. In eight patients the findings were completely normal only two specimens were characterized by

definite inflammatory changes. (6 figures.)

K. W. Ascher.

Spaeth, E. B. **Correction of some forms of acquired ptosis.** *Plastic and Reconstructive Surg.*, 1947, v. 2, Jan., pp. 37-43.

The greater number of cases of acquired ptosis fall into three surgical subdivisions. In the Hess technique the resultant cicatricial bands bring the desired result; in the Reese technique the orbicularis is utilized; and in the third a classical advancement of the levator is combined with the resection and tarsectomy to increase the effectiveness of the levator.

The Hess procedure is indicated in the correction of ptosis associated with any type of lid reconstruction. Acquired ptosis where trauma has produced thick, ptotic lids and cicatrices, and where little orbicularis action remains, calls for the Hess operation. Where trauma has severed the levator, the orbicularis should be transplanted into the occipitofrontalis muscle. If the orbicularis is destroyed a transplant of fascia lata may be made. When the levator is only partially severed, reattachment is not difficult.

Surgical suggestions are made for the treatment of other anatomic defects associated with acquired ptosis. Five cases are presented.

TUMORS

Babel, J. **Orbital chronic inflammation and pseudo-tumors.** *Ann. d'Ocul.*, 1946, v. 179, Oct., pp. 540-550. (See Section 13, Eyeball and orbit.)

Laval, Joseph. **Hemorrhage in sarcoma of the choroid.** *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 607-609.

(See Section 7, Uveal tract, sympathetic disease, and aqueous humor.)

Reese, A. B. **Pigmented tumors.** (The de Schweinitz lecture.) *Amer. Jour. Ophth.*, 1947, v. 30, May, pp. 537-565. (16 figures, 1 table, 56 references.)

16

INJURIES

Arentsen, Juan. **A case of sympathetic ophthalmia cured with penicillin.** *Arch. Chilenos de Oft.*, 1946, v. 2, March-April, pp. 118-123.

The patient was a boy of 12 years, injured in the right eye with a dynamite cap. The penetrating corneal wound was badly infected, and the condition improved rapidly under penicillin given locally and generally. It is difficult to understand why the author speaks of a case of sympathetic ophthalmia, since the injury had occurred only five days earlier, and the left eye remained completely healthy.

W. H. Crisp.

Vail, Derrick. **Early treatment of ocular injuries.** *Industrial Med.*, 1947, v. 16, April, pp. 173-174.

The author appeals to the industrial surgeon for early treatment of ocular injuries which rank second to none in importance. He clearly outlines the proper procedures to be used.

O. H. Ellis.

Van Arsdell, P. M. **First aid for chemical eye injuries.** *Industrial Med.*, 1947, v. 16, April, pp. 188-196.

The ocular reactions to acids, alkalies and salts are extensively tabulated, and our knowledge of these effects widened. The fact is stressed repeatedly that no treatment of chemical eye injury compares with immediate copious irrigation with water. This is the most effective first-aid measure.

O. H. Ellis.

MISCELLANEOUS

EYE-BANK FOR BOSTON

An affiliated Eye-Bank has been organized in Boston and is ready to serve the needs of New England. It is located in the Massachusetts Eye and Ear Infirmary building at 243. Charles Street. Seven hospitals in the Boston area and one in Maine have already become affiliated with it. The general public in New England is being urged to sign forms, available from the Boston Eye-Bank, indicating their willingness to donate their eyes for use after death.

Henry Hixon Meyer, William S. Ballard, and Dr. Edwin B. Dunphy constitute the executive committee of the Boston Eye-Bank's Board of Sponsors. The board includes leading ophthalmologists throughout New England; business, industrial, and religious leaders; and representatives of the eye departments of various hospitals in the area.

STUDY COUNCIL COURSE

On June 20th the summer course in ophthalmology given under the auspices of the Ophthalmological Study Council opened at Westbrook Junior College, Portland, Maine. The course, which will run until September 13, covers such subjects as anatomy, pathology, bacteriology, physiologic optics, neuro-ophthalmology, surgical principles, glaucoma and general diseases, and ophthalmoscopy. There is laboratory work in pathology and optics and practical work in slitlamp, perimetry, and refraction.

TRAIN MOTHERS OF BLIND CHILDREN

The Iowa State Commission for the Blind is planning to offer a week of training for mothers with visually handicapped children under the age of five years. It will be held at the Iowa School for the Blind at Vinton. Designed to

acquaint mothers with the type of training which will be beneficial to their children, the course consists of a preschool training program. There is to be no registration fee, and board and room will be provided for both mothers and children. Matrons will look after the children while the mothers attend the meetings. Further information may be obtained from Mr. Leslie M. Hays, Superintendent, Iowa School for the Blind, Vinton.

EYE-BANK FELLOWSHIPS

Seven fellowships for research and 16 scholarships for its training course have been granted during the past year by The Eye-Bank for Sight Restoration, Inc. Physicians from other countries who have received awards include: Dr. John P. Blum, Geneva, Switzerland; Dr. Walter Kornbleuth, Jerusalem; Dr. Geminiano de Ocampo, Manila; Dr. M. K. Yuo, Fukien, China; Dr. P. K. Kuo, Shanghai; and Major M. M. A. Dubash, Bombay, India.

SOCIETIES

ANTIBIOTIC THERAPY DISCUSSED

The Reading Eye, Ear, Nose and Throat Society and the Reading Dental Society met jointly on May 21st. The speaker was Dr. John A. Kolmer of Philadelphia. His topic was "Antibiotic Therapy in Relation to Dentistry and Ophthalmology."

NEW OFFICERS ELECTED

At the May 5th meeting of the Louisiana-Mississippi Ophthalmological and Otolaryngological Society at Biloxi, Mississippi, Dr. Noel Simmonds of Alexandria, Louisiana, was elected president and Dr. Edley H. Jones of Vicksburg, Mississippi, was reelected secretary. The 1948 convention will be held in New Orleans, Louisiana.

CAROLINAS TO HAVE JOINT MEETING

The second annual meeting of the North Carolina Eye, Ear, Nose, and Throat Society and the South Carolina Society of Ophthalmology and Otolaryngology will be held at the Hotel Skyland, Hendersonville, North Carolina, on September 15th to 18th. The first two days of the program will be devoted to ophthalmology, and the speakers will be Dr. Harold Brown, Dr. John H. Dunnington, and Dr. Brit-

tain F. Payne of New York, and Dr. Jack S. Guyton of Baltimore.

Information about this meeting may be obtained from the officers of either Society. Those representing North Carolina are: Dr. V. K. Hart, president, Charlotte; Dr. W. E. Brackett, vice-president, Hendersonville; and Dr. J. A. Harrill, secretary-treasurer, Winston-Salem. The South Carolina officers are: Dr. Ruskin G. Anderson, president, Spartanburg; Dr. S. Harry Ross, vice-president, Anderson; and Dr. Roderick Macdonald, secretary-treasurer, Rock Hill.

NEW YORK SOCIETY OFFICERS

The newly elected officers of the New York Society for Clinical Ophthalmology are: Dr. Daniel Kravitz, president, and Dr. Leon Ehrlich, 211 Central Park West, New York City, corresponding secretary.

MILWAUKEE HOLDS ANNUAL MEETING

The annual meeting of the Milwaukee Ophthalmic Society was held on May 27th. The following members were nominated as officers for the coming year: Dr. Frank Treskow, president; Dr. S. S. Blankenstein, vice-president; and Dr. George Dunker, secretary-treasurer. Dr. Mark Bach, Dr. J. P. Wild, and Dr. Meyer Fox were nominated as directors. Motion pictures of fishing in Canada were shown by Dr. Herbert Schmidt, and various members of the Society showed travel slides.

CHINESE SOCIETY SPEAKER

When Sir Clutha Mackenzie of New Zealand studied the problems of the blinded soldiers in China at the invitation of the Chinese government, he stopped at West China Union University and addressed a combined session of the Chengtu Ophthalmological Society and the Chengtu Eye, Ear, Nose, and Throat Society.

PERSONALS

AWARDED SILVER MEDAL

The Illinois State Medical Society has awarded a silver medal to Dr. Bertha A. Klien,

associate professor of Ophthalmology, Northwestern University School of Medicine, for the exceptional educational value of her exhibit, "Diseases of the Fundus Oculi," shown at the 1947 meeting of the Society at the Palmer House, Chicago, in May.

DR. BARKAN SPEAKS IN HOLLAND

Dr. Otto Barkan of San Francisco was the guest speaker at the annual meeting of the Netherlands Ophthalmological Society and the Society for the Prevention of Blindness in Amsterdam, Holland, on June 7th and 8th. The subject of his paper was "Glaucoma Operations."

N.S.P.B. VICE-PRESIDENT

Dr. Conrad Berens of New York City was elected vice-president of the National Society for the Prevention of Blindness at the semi-annual meeting of the board of directors.

PROFESSOR FUCHS TO LECTURE

During June and July, Prof. Adalbert Fuchs of Vienna, who is visiting China under the auspices of the UNRRA, will deliver a series of lectures and conduct clinical demonstrations at the Department of Ophthalmology, West China Medical College, Chengtu, Szechwan, China.

TO GIVE DE SCHWEINITZ LECTURE

On November 20, 1947, Dr. Bernard Samuels of New York will give the 10th annual de Schweinitz Lecture before the Section on Ophthalmology of the College of Physicians of Philadelphia. Dr. Samuels' subject will be: "Necrosis of Intraocular Tissues."

MEXICAN SOCIETY SPEAKER

Dr. Joseph I. Pascal will read a paper on "Spherical Equivalent of Cross-Cylinder Tests," at the meeting of the Mexican National Society for the Prevention of Blindness to be held in Mexico City, August 11th to 15th.

ANGIOID STREAKS*

A CLINICAL AND HISTOPATHOLOGIC STUDY

BERTHA A. KLIEN, M.D.

Chicago

Angioid streaks, like all rare lesions of the fundus, pose an especially fascinating problem in the correlation of clinical and histopathologic findings. This is the third histologic report in the ophthalmic literature, and concerns the two eyes of the same individual—one in an earlier stage, the other in a well-advanced stage of this disease—which afford an opportunity to add several new facts to the present knowledge of angioid streaks. Five clinical cases are also presented, two with associated pseudoxanthoma elasticum of the skin, and one with associated osteitis deformans (Paget's disease). Special emphasis will be placed upon the correlation of the rather varied clinical details in the different stages of the disease with the underlying histopathology.

Almost five decades of speculation about the pathologic process in angioid streaks passed between the first description of the clinical picture by O. Plange,¹ in 1891, its naming by H. Knapp,² in 1892, and the first histologic study, in 1938, by J. Boeck³ of the I. Eye Clinic in Vienna. From this first report it was obvious that one of the outstanding histologic features of this condition was breaks and dehiscences of the lamina basalis of the choroid (Bruch's mem-

brane). The conclusion, however, that these breaks and dehiscences represented the essential basis for the clinical visibility of the streaks was erroneous. Breaks in Bruch's membrane have not been unknown. They have been discovered in histologic sections of a variety of conditions such as high myopia, arteriosclerosis of the choroid, and disciform macular degeneration, in all of which only a small proportion of the breaks or none at all were visible clinically. It was realized (Hagedoorn,⁴ Klien⁵) that a mere defect in the lamina basalis alone would not be sufficient to produce the clinical picture of angioid streaks, but that something further would be necessary; that is, an alteration of the membrane which would render it opaque and make the defects visible by contrast.

Hagedoorn,⁴ in the second histologic study of angioid streaks in 1939, proved painstakingly and conclusively that there is a diffuse degeneration of the elastic fibers of Bruch's membrane, which presumably impairs its translucency and makes ruptures in the degenerated membrane visible by contrast. A suggestion of this kind, but without actual proof, had been already made by Groenblad,⁶ who emphasized for the first time that the frequent association of angioid streaks and pseudoxanthoma elasticum of the skin may point to a systemic degeneration of the elastic tissues of the body. Prior

*From the Department of Ophthalmology, Northwestern University Medical School. Read before the Chicago Ophthalmological Society, February 17, 1947.

to Groenblad's publication, this association had been noted as far back as 1903, by two French authors, Hallopeau and Laffitte,⁷ but was not further emphasized.

The clinical picture of angioid streaks has been presented so often and so well that a general description of it is omitted here. Three of the following reports of

regions appeared finely granular. The right fundus is shown in Figure 1. Between the disc and the upper portion of the circular angioid streak, there was an opaque yellowish discoloration. Within the broadest streak on the temporal side there was a fine lighter-red pattern, as if of visible choriocapillaris.

During five years of observation, there was no deterioration of the central vision. The appearance of the maculas remained unchanged, but in the inferior nasal periphery of the right eye, there developed a yellowish-gray crescentic area with discrete and confluent white dots. The visual fields revealed some enlargement of the blind spots, but were normal otherwise.

There was no pseudoxanthoma elasticum. The patient suffered from coronary vascular disease. Blood pressure was 130/80 mm. Hg.

*Case 2.** Sch. E., a woman, aged 40 years, entered the eye clinic of Rush Medical College complaining of bilateral, progressive loss of vision for the past two years, the onset of which was characterized by marked metamorphopsia. At the age of nine years, she had also noted cutaneous lesions in the form of small yellowish papules at the base of the neck. After the age of 30 years, similiar lesions developed in the groins and the axillae. There was no history of ocular trauma or inflammation. The family history was irrelevant. Corrected vision was: R.E., 0.5; L.E., 0.3—1. The external ocular findings were normal, as were the optic discs and retinal vessels. In the right fundus, there was a semicircular arrangement of reddish-brown angioid streaks with characteristic ragged outline. Radial extensions emerged from several places

Fig. 1 (Klien). Right eye of Case 1. Very early stage of angioid streaks. There is an incipient, opaque, yellowish area above disc.

patients, however, are accompanied by illustrations depicting the disease in early, advanced, and late stages, to facilitate reference to some of the clinical details in the course of the histopathologic description.

CASE REPORTS

Case 1. B. A., a man, 56 years of age, entered the eye clinic of Rush Medical College with the complaint of presbyopia. The corrected vision in each eye was 1.2 and J1. The external ocular findings, optic discs, and retinal vessels were normal. Both discs were surrounded by a circle of reddish-brown angioid streaks from which numerous radial extensions originated. There was no visible macular lesion in either eye, but the posterior polar

* This patient was presented by Dr. Nomland and Dr. Klien at the Chicago Dermatologic Society, October 19, 1932.

and could be followed far into the periphery. Near the temporal margin of the disc there was a grayish, poorly defined choroidal lesion, 3 by 4 disc diameters in size, with irregular pigment inclusions and some superimposed connective tissue.

In the left fundus (fig. 2), there were similar but more advanced pathologic findings. The macula was occupied by a gray, ill-defined plaque, 1 by 1 disc diameters in size, into which a large reddish-brown streak seemed to merge. It was almost surrounded by a zone of fine yellowish dots of moth-eaten appearance. Between disc and macula there was a spiderlike formation of streaks, and in its neighborhood, there were several small, deep, flat hemorrhages. Within this broad streak, choroidal vessels of normal appearance were distinctly visible. There were also several areas of pigment proliferation and of diffuse opaque yellowish discoloration. In several light-colored areas, choroidal vessels were distinctly visible, and one of them, above the disc, appeared sclerosed.

In the periphery of both fundi there were fine, diffuse, granular pigmentary disturbances, and, in general, the posterior polar regions between the streaks had a peculiar veil-like haze.

The patient was observed for two years, during which time hemorrhages recurred around the macular lesions. One retinal vessel, crossing a large streak, was, at first, observed to have a sheathing with a grayish-black pigment. This disappeared in the course of several months.

The patient had an essential hypertension with blood pressure around 158/88 mm. Hg. The blood-cholesterol level was normal. The diagnosis of bilateral angioid streaks with associated pseudoxanthoma elasticum was made, and the diagnosis of the skin lesion was confirmed by Dr. R. Nomland in the Department of Derma-

tology. Dr. Nomland said that a biopsy specimen of the skin stained with orcein and hematoxylin showed, in circumscribed areas in the subpapillary and middle cutis, elastic fibers occurring in coils, which were thickened, broken, and fragmented. These fibrils took an intensive blue stain with hematoxylin and

Fig. 2 (Klien). Left eye of Case 2. Advanced stage of angioid streaks. There are beginning macular lesions in the form of gray area surrounded by yellowish spots with moth-eaten outline. Sclerotic choroidal vessel visible above disc. Choroidal vessels visible within broad angioid streak.

turned dark brown under the influence of silver nitrate, suggesting the presence of calcium (Nomland and Klein⁸).

Several years later Finnerud and Nomland⁹ published further work on pseudoxanthoma elasticum, in which they demonstrated the presence of calcium in the form of the phosphate by staining methods, quantitative chemical analysis, and microchemical means. This is especially mentioned here because of the parallelism between skin and eye findings. Although the presence of calcium is only secondary to the primary elastic degeneration in skin and eye, it evidently plays a role in producing the great variety of findings

which characterize the later stages of the ocular disease.

*Case 3.** N. A., a man, 42 years of age, was sent by his dermatologist for ocular consultation. At the time of his first visit 15 years ago, he complained of failing left vision of several years' duration. He had an extensive pseudoxanthoma elasticum of the skin and attacks of purpura

Fig. 3 (Klien). Left eye of Case 3. Late stage of angioid streaks. There is a disciform macular lesion, extensive opaque yellowish color with pigment flecks below disc.

hemorrhagica. The right vision was 1.2; the left, 4/200. The external ocular findings, discs, and retinal vessels were normal. There was extensive angioid-streak formation without a macular lesion in the right fundus. The left fundus is pictured in Figure 3. Within the broadest streak, between macula and disc, several choroidal vessels were visible. Many of the streaks had light-colored centers but lacked visible choroidal details. There was a disciform macular lesion. Adjoining the inferior margin of the disc, there was an opaque yellowish-white area, stud-

ded with numerous small brown dots, which extended far into the lower fundus periphery and on the temporal side followed the outline of a broad radial angioid streak.

A recent report from the patient states that the right eye also has now lost its central vision and that the pseudoxanthoma covers most of the body. The outbreaks of purpura have become less frequent, but two years ago an enlargement of the spleen and polycythemia vera were discovered.

Case 4.† J. S., a man, aged 49 years, entered the eye clinic of Rush Medical College complaining of bilateral progressive loss of vision for the past two years. For the past seven years he had noted a slowly advancing enlargement of the head with subsequent impairment of hearing and a diminution of his height. A diagnosis of osteitis deformans was made and confirmed.

At the time of the first visit, corrected vision was: R.E., 0.4 and J1 at 6 inches; L.E., 0.1 and no Jaeger. There was very high bilateral mixed astigmatism. Aside from an extremely wide interpupillary distance, the external eye findings were normal. Both optic discs showed a marked typus inversus, but they and the retinal vessels appeared normal. Around both discs there were incomplete circles of angioid streaks, which varied in color from reddish-brown to yellow. There were a few radial extensions. In the left eye, there were scattered deep hemorrhages, which appeared to be in the same level as the streaks. The fundus picture in both eyes was, however, dominated by the macular lesions, which consisted of well-defined, slightly prominent masses with inclusion of brown pigment.

There was a large paracentral scotoma in the right field, a central scotoma in the

* Dr. O. H. Foerster, Milwaukee, who has had this patient under observation for the past 15 years, has supplied all but the ocular data.

† This patient was presented at the Chicago Ophthalmological Society, April 4, 1941.

left field, and a moderate, irregular, concentric contraction of the peripheral visual fields.

During four years of observation, there were repeated deep hemorrhages in and around the macular lesions and the vision deteriorated to 1/200 in the right eye; 2/200 in the left eye. There was a marked increase of phosphatase in the blood (24 Bodansky units as compared to a normal of 5 to 8), a finding which is of great differential-diagnostic importance, as it is already present in the subclinical forms of osteitis deformans.

In addition to the symptoms of osteitis deformans, the patient had marked generalized arteriosclerosis, especially tortuous and thickened temporal arteries. Enlarged veins and arteries had eroded the skull in places, and one large vein over the right frontal area was pulsating.

The association of angioid streaks and Paget's disease was first emphasized by Terry,¹⁰ who collected four cases from the literature and added five of his own. Two more cases have since been reported by Lambert,¹¹ and one by Morrison.¹² This association may be much more frequent than reports in the literature lead one to believe, because in many reports of Paget's disease, the patient's defective vision is stated without investigation of its cause. Two of the most interesting reports in this connection concern two patients with osteitis deformans and multiple calcium deposits in various, otherwise normal, soft tissues and inner organs (Wells and Holley,¹³ Seligman and Nathanson¹⁴). Calcifications of healthy tissues are difficult to explain, and it is usually assumed that circulatory disturbances favor it. According to some authors, the increased amount of phosphatase may have a close causal relation to the deposition of calcium. There is rarely a hypercalcemia in Paget's disease, although the calcium-phosphorus balance is said to be

disturbed. As some one expressed it: "The bone lesions surrender calcium to the tissues." It is interesting that the deposition of calcium, whenever present, was found in otherwise healthy tissues. It could, therefore, also be deposited in an otherwise healthy Bruch's membrane leading to fragility and angioid streaks, without preceding degeneration of elastic tissues. So far no association of Paget's disease with pseudoxanthoma elasticum, which would point to a selective degeneration of the elastic tissue, has been reported. Angioid streaks and Paget's disease have in common, however, frequent association with marked generalized arteriosclerosis, and circulatory disturbances on this basis may predispose to calcification of various tissues. Each patient with angioid streaks, especially those without associated pseudoxanthoma elasticum, should be tested for the subclinical forms of osteitis deformans by determining the phosphatase level in the blood, and each patient with Paget's disease should be submitted to a periodic fundus examination.

Case 5. E. G., a woman, aged 62 years, entered the eye clinic of Rush Medical College with the complaint of presbyopia. The vision in the left eye had been poor all her life.

Corrected vision was: R.E., 0.8 + 3 and J1; L.E., hand movements and correct light projection. External ocular findings in the right eye were normal. The cornea of the left eye was smaller than normal with numerous medullated nerve fibers. There were congenital nuclear and anterior-polar cataracts and between the 11- and 12-o'clock positions, vitreous herniated slightly through a congenital coloboma of the lens. The fundus was not visible.

The right optic disc was normal. There were several circular angioid streaks around it with three radial extensions, the

longest of which merged peripherally with a dull-red area, which was surrounded by a grayish discoloration. The macula was normal.

There was no pseudoxanthoma elasticum of the skin. This case is included because of the associated malformations of the other eye. Malformations in association with angioid streaks are mentioned by Boeck, who found vascular malformations in the form of opticociliary arteries in 3 of 14 cases with angioid streaks. Malformations were also found in our Case 4.

Case 6. St. J., a man, 53 years of age, was admitted to the neurologic service of Passavant Hospital in a serious condition, with the history of attacks of dizziness and speech difficulty of six months' duration. At this time his eye grounds were examined by Dr. Derrick Vail, who found angioid streaks in both eyes, a well-developed disciform lesion in the left macula, and a similar incipient lesion of the right macula. No fundus paintings or photographs were made because the patient was moribund.

Two reports of previous ocular examinations were obtained, one from (Dr. Gradle's office) 12 years ago, which mentioned an active, elevated lesion in the left macula with fresh hemorrhages, and a lesion resembling a healed choroidal rupture in the right fundus. Vision at that time was: R.E., 1.5; L.E., 10/200. Years later the patient was examined in the Mayo Clinic, where the diagnosis of bilateral angioid streaks was made.

The salient features of the general autopsy report were: arachnoiditis with cerebral hemorrhages, severe arteriosclerosis with ulceration and calcification in the aorta, and mild nephrosclerosis. There was no pseudoxanthoma elasticum of the skin.

Immediately after death, injections of a 10-percent solution of formaldehyde

were made into the orbital tissues around the eyeballs and, after enucleation, both globes were placed in a 10-percent neutral solution of formaldehyde for fixation. The external measurements of both eyeballs were equal and normal. Prior to the embedding, the right globe was cut into an anterior and posterior half, considering the possibility of photographic registration of any visible details of the eye ground. The retina, however, although in situ, was completely opaque and drawn into numerous minute radial folds around optic disc and fovea, making choroidal details invisible. The left eye was opened by a superior and inferior section. All intraocular structures were in situ. In the macula there was a slightly elevated whitish lesion, measuring 1 disc diameter, in the vertical, and $1\frac{1}{2}$ disc diameters in the horizontal diameter (fig. 4). It was surrounded by a pigmented zone which was densest and broadest above and nasally, where it measured 1 disc diameter. In various portions of the fundus, there were lighter, yellowish areas, especially above the disc and the disciform macular lesion; other portions, particularly within 3 to 4 disc diameters around the disc and below the macular lesion, gave the impression of a grayish veil. Adjacent to the disc, there were fine radial folds of the retina which obscured the deeper-lying details in this area. There were two distinctly visible angioid streaks; one, broad and short, radiated from the peripapillary area into the inferior temporal sector. The broad portion had a yellowish color and dark, ragged outlines, and in only one place, along the upper outline, there was a light accompanying line. At a distance of about 2 disc diameters from the optic papilla, the streak faded out as a narrow grayish-brown line. The other visible streak radiated from the peripapillary area of the superior temporal sector and could be fol-

lowed far out into the periphery as a ragged yellowish band, with brown borders in several places. A short branch from this upper streak joined the disciform macular lesion. The superior calotte, which was removed from this globe, contained the end of this angioid streak, and was embedded in paraffin, while the main portions of both eyes were embedded in celloidin.

Histologic findings. Both eyes were sectioned from above downward. Of the right eye only the posterior half has, as yet, been sectioned. The anterior segment of the left eye was normal. There were no calcium deposits in the corneal or conjunctival epithelium. The pathologic findings in the posterior segments of both eyes were similar, only further advanced in the left eye, and they shall be discussed together as far as possible.

Since the pathology of angioid streaks centers around the lamina basalis of the choroid, a few general remarks about this structure are in place. The inner lamella of this membrane is of a homogeneous cuticular type and is considered as the basal membrane of the pigment epithelium. The outer portion consists of a plexus of fine elastic fibers which are connected with the abundant elastic fibers of the capillary interstices in the choroid. In the posterior segment these two portions are joined together by an invisible cement substance. In most sections the cuticular layer is more difficult to see than the elastic lamella.

In the sections of both eyes, stained with hematoxylin-eosin, attention was focused immediately upon the deep-blue stain of the lamina basalis, which stood out as a broad, easily visible line throughout the posterior polar region. Toward the equator this deep stain ceased to be homogeneous but became spotty and in the periphery the membrane had an inconspicuous normal appearance.

There were numerous breaks in the membrane, which increased in number toward the posterior polar regions. Some of these were quite small and affected only the outer elastic portion of the membrane, while the choriocapillaris under

Fig. 6 (Klien). Paraffin section, hematoxylin-eosin, $\times 450$. Multiple fractures, mostly artefacts, of Bruch's membrane, showing its extreme fragility.

them, the inner cuticular portion, pigment epithelium, and retina were completely intact. The edges of the breaks were often abrupt with slightly frayed ends (fig. 5); others were oblique with slanting margins (fig. 8). Visible connections of some of these edges and of entire short fragments with the elastic network of the choriocapillaris had in many instances caused their displacement backward. In one area an artefact had resulted in some tangential sections of Bruch's membrane in a portion, containing narrow ruptures, which had the almost identical shape of the clinically visible streaks (fig. 9).

In addition to these narrow ruptures there were wide gaps in the lamina basalis over still well-preserved choriocapillaris (fig. 5), within which choroidal blood vessels would be visible clinically if the pigment epithelium did not carry much pigment. The deep hematoxylin stain of the membrane suggested the presence of calcium deposits, which were definitely

Fig. 7 (Klien). Spotty black stain of Bruch's membrane with Kossa test for calcium ($\times 400$). Thick cuticular layer under pigment epithelium.

demonstrated by a positive Kossa reaction (fig. 7). With this method, entire fragments, especially those dislocated into the deeper layers of the choroid, stained diffusely black, while in the portions of the membrane without gross lesions, the black stain indicating calcium was as spotty as the hematoxylin stain of corresponding areas in adjoining sections. In sections stained with orcein, the most peripheral portions of the lamina basalis took the elastic stain homogeneously, while a spotty distribution of it appeared farther back, and in the posterior polar regions long stretches of the membrane stained only faintly. By careful study of adjoining sections, it was possible to decide that the same portions of the membrane, which took a heavy hematoxylin stain and scarcely stained with orcein, indicated an almost complete degeneration

of the elastic fibers in these places. In other portions, which stained well with orcein, high magnifications revealed wavy, curly, and clumplike elastic fibers, particularly at the margins of some breaks. The fragility of the membrane, which must be intensified by the calcium deposits into the degenerated elastic portion, was well demonstrated by a very thin paraffin section (fig. 6) in which multiple, obviously artificial ruptures occurred.

Two factors may be responsible for the early calcification of the membrane. One is the affinity of degenerated elastic tissue for calcium salts, which is well known in general pathology; the other is the serous extravasation, due possibly to irritation of the choroidal capillaries, which was found in all of the histologic specimens of angioid streaks and which produces

bleblike detachments of the pigment epithelium from Bruch's membrane (fig. 8), and which may act similarly to serous fluid following circulatory disturbances in other tissues—a condition known to favor deposition of calcium.

Another special stain that gave a positive reaction in the lamina of both eyes was the Turnbull blue stain, one of the most reliable tests for the presence of iron. The lamina of the right eye stained faintly blue, that of the left eye intensely blue throughout the posterior polar region; while in a control eye with exten-

Fig. 8 (Klien). Oblique break in and beginning dislocation of small fragment of Bruch's membrane. Serous fluid under pigment epithelium. Choroid and retina normal.

sive posttraumatic retinal and subretinal hemorrhages, the lamina remained unstained. This, and the fact that the only retinal hemorrhage was found in the right eye with the less-advanced stage of the disease and the weaker iron stain in the lamina, suggests that not local hemorrhages but other metabolic disturbances are the cause for the deposition of iron salts in the lamina.

The structure which next to Bruch's membrane showed the most obvious

changes was the pigment epithelium. While it was normal over many of the small ruptures, it became irregular over the larger dehiscences, and small groups of its cells lost their pigment content,

Fig. 9 (Klien). Incidental tangential section of Bruch's membrane with cracks of similar shape as those clinically visible.

mostly without disruption of its continuity.

Through many breaks in the lamina basalis, capillaries and fibroblasts had grown between it and the pigment epithelium, mixing with new glial tissue and forming crestlike elevations which could be followed through many sections running alongside the ruptures of Bruch's membrane (fig. 10). A similar, newly formed tissue, arranged in mounds, occupied the left macular area, where it contained some amorphous hyalin and a plate of bone.

It was interesting to note that, under these hypertrophic lesions, Bruch's membrane was unusually well preserved and that the newly formed tissue preferred to grow upon the still-preserved membrane as a base rather than to fill the gaps over the ruptures (fig. 10). Most of the concentric lesions around the optic discs consisted of these hypertrophic streaks

rather than the simple ruptures. Although rarely missing, the pigment epithelium over these crests and mounds was usually degenerated into flat, nonpigmented cells. At the corners of some of these crests, granular calcium or amorphous hyalin granules were deposited. The latter and the collagenous portions of these hypertrophic lesions were brought out well by

calcified fragments of Bruch's membrane. Many of the choroidal and posterior ciliary arteries were normal; in others there were occasional defects or hypertrophic areas of the internal elastic lamella and spotty hypertrophy of media and adventitia. Here one could take issue with one of Hagedoorn's⁴ remarks about the choroid. He says (p. 947): "The

Fig. 10 (Klien). Hypertrophic lesions accompanying dehiscences of Bruch's membrane. Pigment hyperplasia and hyalin deposits at extreme left.

the Van Gieson stain. There were also extensive areas within which a homogeneous, deeply pink-staining layer of cuticular appearance and of slightly varying thickness was found between the lamina and the pigment epithelium. In the left eye they corresponded to the light, yellowish segments of the fundus sketched in Figure 4. Circumscribed excrescences of this cuticular substance covered here and there small ruptures of the lamina. Another type of faintly pink-staining, somewhat granular substance, underneath bleblike detachments of the pigment epithelium, was interpreted as slightly coagulated serous fluid.

The choroid appeared normal under the unbroken membrane and under small ruptures. Under more extensive dehiscences and especially under the hypertrophic lesions, the capillary layer was missing and in many places fibroblastic granulomas had formed around displaced

choroid is surprisingly inactive in closing the ruptures of Bruch's layer." A good reply would be: "Why expect it of the choroid?" There are no cells in the choroid which are vitally interested in an intact lamina basalis. The pigment epithelium is the structure whose health and continuity, so important for the visual function, is endangered by damage to the lamina, and, indeed, much of its above-described activity could be interpreted as reparative.

The retina appeared normal except over some of the hypertrophic lesions, where the first and second neurons were extensively damaged. There was one small subretinal hemorrhage, temporal to the macula of the right eye. Sclerosis of the retinal arteries was even less marked than that of the ciliary arteries. The optic nerves were normal excepting several hyalin bodies in the temporal half of the left nervehead.

SUMMARY

The anatomic study of two eyes with angioid streaks confirmed, on one hand, previous findings made by Boeck and Hagedoorn; on the other hand, it permitted the addition of several new observations, mainly because our specimens were unusually well preserved and because a detailed sketch of the posterior segment of one of the enucleated eyes facilitated a certain amount of direct correlation of the macroscopic and microscopic picture.

Previously recorded basic findings confirmed by our study are:

1. The diffuse degeneration of the elastic portion of Bruch's membrane, which leads to ruptures and dehiscences and may, as such, suffice to render the membrane opaque. A pertinent example of an ocular lesion in which a normally transparent tissue becomes opaque through degeneration of elastic fibers is the pinguecula.

2. The coexisting vascular disease, which in the eye affects mostly the posterior ciliary and choroidal vessels. It was found by both Boeck and Hagedoorn. However, Hagedoorn's statement, that the picture of the sclerotic arteries in eyes with angioid streaks differs from that in other eyes with simple choroidal sclerosis, can be accepted only with reservations. Hagedoorn's patient had an arterial hypertension of 200/140 mm. Hg at the age of 48 years, and the uniform thickening of the media and internal elastic lamella of the ciliary and choroidal arteries in his patient goes well with this clinical symptom. In both of our specimens the picture was that of the simple senile, involutionary type of sclerosis, characterized by spotty but often considerable hypertrophy of adventitia and media, and by a slightly rarefied, or normal, or occasionally thickened, in-

ternal elastic lamella. The clinical findings, in a number of patients with angioid streaks, of marked generalized arteriosclerosis or arteriosclerotic heart or cerebral disease without arterial hypertension, favor the conception of a premature senile sclerosis.

3. The positive iron stain of the lamina basalis in the posterior polar region was also obtained by Hagedoorn but not by Boeck, who used a less reliable staining method. In our case it was more pronounced in the eye with the more advanced stage of the disease, indicating that the iron salts are deposited later than the calcium salts.

Our own observations concern mainly the morphology of the early degeneration and ruptures of Bruch's membrane and the correlation between clinical and histologic lesions.

1. The earliest ruptures were limited to the elastic portions of the membrane, leaving its cuticular layer, the pigment epithelium, and the overlying retina completely intact.

2. The early defects in the membrane were of two kinds, namely, abrupt vertical severances of the appearance of true breaks (fig. 6) and oblique dehiscences (fig. 8), depending, perhaps, upon whether the break occurred in a portion which was already calcified or in one which had undergone, as yet, only a degeneration of the elastic tissue.

3. A definite proof of the calcification of the membrane was obtained through a positive Kossa stain. The calcification of the membrane in the earlier stages is as spotty (fig. 7) as the elastic degeneration shown by the orcein stain.

4. A dislocation of the edges of the breaks or of entire calcified fragments of the membrane into the deeper layers of the choroid was observed in many places, brought about by their intimate connection with the elastic fibers of the chorio-

capillaris. During this process of dislocation, the first irritative response from pigment epithelium and choriocapillaris seems to appear, which later on gives such variety to the picture. The frequent and often considerable separation of the pigment epithelium from Bruch's layer was caused in different places, by three different kinds of material: (1) A cuticular substance produced by the epithelium cells themselves; (2) a serous extravasation from the choriocapillaris; or (3) a mixture of glial and fibrous tissue with capillaries, derived from pigment epithelium and choroid, respectively.

The correlation of clinical and pathologic findings is based partly upon our present knowledge of similar or analogous conditions already correlated in this manner; partly upon the direct comparison of details in the gross drawing and the corresponding place in the histologic sections of Case 6. On this basis correlation with histologic findings of the following clinical details can be made:

1. The early streaks of reddish-brown color, some with visible choroidal details between their outlines. They appear histologically as simple ruptures or dehiscences in a degenerated lamina basalis. Depending upon the age of the rupture, choriocapillaris or larger choroidal vessels are clinically visible within them. Their color is a lighter or darker red, depending upon the pigment content of the still intact, if not normal, pigment epithelium and that of the choroidal stroma. The adjacent fundus is not discolored, but merely not transparent (fig. 1 and fig. 5).

2. Reddish- or grayish-brown streaks with light accompanying lines as shown in the drawing (fig. 4). In the corresponding place in the histologic sections, and in numerous other places, there were ruptures in Bruch's membrane which were accompanied by linear crests of newly formed tissue between pigment

epithelium and lamina basalis. The hyalin deposits at the margins of some of these crests would intensify the light appearance of these hypertrophic streaks clinically.

3. Yellowish streaks (fig. 4) with or without dark or light accompanying lines. Through many adjacent sections narrow but thick, avascular, cuticular formations could be followed over narrow ruptures of the lamina, which clinically had the yellow color of drusen. The pigment epithelium was rarely missing over them, but had lost most of its pigment content and often consisted of only one layer of flat degenerated cells.

The most interesting correlations could be made regarding the appearance of the fundus in general. The two extremes in this respect were the diffuse, opaque, gray and diffuse, opaque, yellowish areas.

The gray areas corresponded to the layers of homogeneous, deeply pink-staining substance between intact pigment epithelium and lamina, which appeared to be due to an overproduction of cuticular substance similar to the basal membrane of the pigment epithelium and the well-known drusen. In the lamina covered by this substance, there usually were many ruptures, and one was reminded of nature's attempts to maintain continuity as, for instance, in the cornea, where endothelial cells become overactive over tears of Descemet's membrane, producing thick layers of a Descemet-like substance and endothelogenous connective tissue. The epithelium over these areas was deeply pigmented and together with the two opaque layers under it—the degenerated elastic lamella and the thick cuticular layer—it appeared clinically as an opaque gray haze (figs. 2, 4, and 7).

The diffuse, opaque, yellowish areas corresponded to similar, perhaps slightly thicker, diffuse cuticular deposits, over

which the epithelium had lost its pigment content, so that the color of the underlying plaques became more evident (fig. 3). The yellow lesions appeared to be the oldest and resulted from the slowly progressive degeneration of the pigment epithelium over the extensive cuticular plaques.

The degeneration of the pigment epithelium is at first limited to isolated groups of its cells and this fact, demonstrable in the sections, may well be responsible for the light-colored dots, which appear within the gray areas and which have the color of drusen, but very unlike drusen, have a moth-eaten outline (figs. 2 and 8). In an advanced stage of this degeneration, a few remaining pigment-bearing cells would be visible as dark spots on a yellowish background (fig. 3).

CONCLUSIONS

The pathogenesis of angioid streaks is based upon an abnormal fragility and opacification of the lamina basalis of the choroid. The natural variations of the intraocular pressure by muscular action or slight pressure upon the eyeball may, in such eyes, cause breaks in the membrane, the margins of which are clinically visible because the membrane has lost its translucency.

In all anatomic studies so far, the basis for this fragility and opacification of Bruch's membrane has been revealed to be primarily a degeneration of its elastic portion, corresponding to a general inferiority of the elastic tissue of the body,

as the frequent association with pseudo-xanthoma elasticum of the skin and with severe, degenerative vascular disease indicates. Theoretically, however, deposits in the membrane of any kind, such as calcium, iron, or magnesium salts following a disturbance of tissue metabolism with or without coexisting constitutional disease, could also deprive the membrane of its transparency and elasticity. In angioid streaks associated with osteitis deformans, for instance, the sequence of events may be slightly different from that in the eyes studied histologically up to the present time. Deposition of calcium salts into a normal lamina basalis, similar to calcification of other healthy tissues in patients with Paget's disease, could also render the membrane fragile and opaque without preceding elastic degeneration. These considerations lead one to speculate about the possible varieties and types of pathologic processes which may affect the lamina basalis in the course of local or constitutional disease.

The clinical picture of angioid streaks represents not only the visible ruptures in Bruch's membrane, but also the multi-form end results of irritation of pigment epithelium and choriocapillaris by the sharp, calcified edges and fragments of the broken membrane. Calcification, therefore, even if secondary to the elastic degeneration in the pathologic process, is essential in production of all except, perhaps, the earliest manifestations of the disease.

SURGICAL TECHNIQUE OF CORNEAL TRANSPLANTATION IN RABBITS*

A DISCUSSION OF THE PROBLEMS ENCOUNTERED AND SUGGESTIONS FOR THEIR SOLUTION

FREDERICK C. STANSBURY, M.D., AND JOSEPH A. C. WADSWORTH, M.D.
New York

The difficulty with which corneal transplantation is successfully accomplished is such that it is seldom attempted on human subjects until the surgeon has acquired some skill with the procedure on experimental animals. The laboratory animal best adapted to this operation, from the point of view of both expense and availability, is the rabbit. All of the pioneers in this new field of ophthalmic surgery (Castroviejo, 1931, etc.; Filatov, 1935, etc.; Thomas, 1930, etc.) have experimented at length on rabbits before proceeding to human patients. These men have written about the different types of operation practised by them individually on human beings, but no one has given a detailed account of the surgical technique employed in keratoplasty on the rabbit. The purpose of this paper is, therefore, to describe in detail the procedure of keratoplasty on rabbits, and the difficul-

ties encountered in this operation, following in general the technique employed by Castroviejo.

TECHNIQUE OF TRANSPLANTATION PROBLEMS ENCOUNTERED

There are problems in transplantation of the rabbit's cornea that are not encountered in the same operation on the human cornea. The rabbit's cornea is thinner than that of man, and this fact makes the placing of the suture, the apposition of the cut surfaces, and the prevention of postoperative bulging more difficult. Anesthesia is a trying procedure and some animals may die on the operating table. It is not feasible to bandage the rabbit's eye, and one must resort to lid sutures—an unsatisfactory method, to say the least, when a pressure bandage is desired. Infection is difficult to prevent in any laboratory animal, and the rabbit is no exception. The postoperative bed-rest and immobility, which are prescribed

* From the Institute of Ophthalmology of the Presbyterian Hospital, New York City.

for the human patient after keratoplasty, are quite obviously out of the question for the rabbit. Once the surgeon is able to overcome these operative difficulties peculiar to the rabbit and is able to perfect his surgical procedure on this animal, he is better prepared to operate upon the human being.

This paper will discuss the operation of square, partial penetrating keratoplasty, and will give an account of the equipment needed, the preparation of the rabbit, the surgical procedure, as well as the management of the difficulties encountered.

EQUIPMENT REQUIRED FOR THE OPERATION

A narrow operating table, not over 12 inches in width and about 4 feet long, will be found very practicable for rabbit surgery. The height can be varied according to the standing or sitting position of the operator. The narrow table is desirable in order that both operator and assistant may be able easily and comfortably to reach the operative field. Any one of the common small instrument tables is satisfactory for the instruments. A good operating lamp of the hammer type provides satisfactory illumination. Other needed items—scrub sink, sterilizer, and so forth—will be found in any well-equipped animal operating room.

The following instruments (fig. 1) are necessary: (1) Castroviejo double-bladed knife, for marking the limits of the window in the recipient's eye and the limits of the graft in the donor eye. (2) Castroviejo's special keratome, 4-mm. wide, for making the initial incision into the anterior chamber in both the recipient and the donor eyes. (3) Modified de Wecker scissors, for cutting the remainder of the incision in both eyes. (4) Spatula, for lifting the graft from the donor eye and placing it in the recipient eye, and also

for last-minute manipulations of the graft when tightening and tying the suture. (5) Fine needle holder, for placing the sutures and tying. (6) Elschmig's fixation forceps, for grasping the episclera and fixing the eye. (7) Fixation forceps, for holding the lids when they are sutured together. (8) Scissors, for cutting the sutures. (9) Mosquito clamp, for holding the moss suture in the center of the window being cut out of the recipient's cornea. (10) Small, straight, toothless forceps for tightening suture. (11) Small, curved, toothless forceps, for tightening the suture. (Often times either the straight or curved forceps will also be used for tying the suture.) (12) Speculum, for separation of the lids. (13) 7-0 double-armed black silk suture with atraumatic needles.

The following solutions and ointments are recommended: (1) 3-percent atropine-sulfate solution. (2) Sodium-pentobarbital solution (45 mgm. per cc. of 10-percent alcohol solution). (3) 4-percent cocaine solution. (4) 20-percent argyrol solution. (5) Sterile physiologic saline solution. (6) 2-percent fluorescein solution. (7) 1-percent sodium citrate solution. (8) Adrenalin solution (1:1,000). (9) Penicillin ophthalmic ointment. (10) 1-percent atropine-sulfate ointment.

PREPARATION OF THE RABBIT

In selecting rabbits for keratoplasty, it is well to obtain an animal weighing five pounds or more. Smaller rabbits may be used, but the operation becomes more difficult on the smaller eye. The rabbits should be obtained sufficiently far in advance of the operation so that they may occupy their new quarters for at least 10 days prior to surgery. A small percentage of rabbits will die when removed to the small cages that constitute their quarters in the medical school or hospital. Further, it has been found that new rabbits do not

Fig. 1. (Stansbury and Wadsworth). Recommended instruments: (1) Castroviejo double-bladed corneal knife; (2) Castroviejo special keratome; (3) modified de Wecker scissors; (4) spatula; (5) needle holder; (6) Elsnig's fixation forceps; (7) fixation forceps; (8) scissors; (9) mosquito clamp; (10) small straight toothless forceps; (11) small, curved, toothless forceps; (12) speculum.

do well postoperatively. On the other hand, rabbits that are well acclimated to their lot will usually take the anesthesia and operation uneventfully.

Six hours prior to the operation, the rabbit is brought to the animal operating rooms, and atropinization of the designated eye is started. A drop of 3-percent atropine-sulfate solution is instilled into this eye each hour for six doses.

Sodium pentobarbital, intravenously, is used for the anesthesia. A solution is made of 45 mgm. of sodium pentobarbi-

tal per cc. of 10-percent alcohol solution, and 1 cc. of the resulting solution is given for each kilogram of body weight. Three fourths of the estimated dosage is slowly injected intravenously $1\frac{1}{2}$ hours before operation, and the remainder of the calculated amount is given one-half hour before operation. This will usually be sufficient, but sometimes it is necessary to introduce a very small additional amount just before fastening the animal into the clamp.

After the second injection of sodium

pentobarbital, the rabbit will lie quiet and submit to the trimming of the hair around the operative field. The hair is removed from an area at least one centimeter wide around the eye. In addition, all the long whiskers on that side of his head are cut. At this time, a drop of 4-percent cocaine solution is instilled into the conjunctival sac.

The rabbit is then placed on the operating table and fastened into the special clamp (fig. 2). The head is adjusted to fit snugly into the clamp, and the screw is turned down. The animal is further immobilized by lashing the extremities to the table (fig. 3). Twenty-percent argyrol solution is then instilled into the conjunctival sac, washed out with sterile saline, and another drop of 4-percent cocaine solution is instilled. A small sterile sheet, with a diamond-shaped opening for the

bladed Castroviejo knife. The blades of this knife have previously been treated with 2-percent fluorescein solution, so that the knife cuts and stains the cornea

Fig. 3 (Stansbury and Wadsworth). Immobilization clamp with the rabbit in position.

Fig. 2 (Stansbury and Wadsworth). Clamp for immobilization of the rabbit.

eye, is then placed over the rabbit and fastened with two towel clamps.

SURGICAL PROCEDURE

Separation of the lids is obtained by means of the standard eye speculum. Care must be taken when inserting the speculum to be sure the nictitating membrane of the rabbit is caught behind one arm of the speculum. The eyeball is then fixated with Elschnig's forceps, and the area to be removed is marked out with the double-

armed Castroviejo knife. The blades of this knife have previously been treated with 2-percent fluorescein solution, so that the knife cuts and stains the cornea at the same time. Using a 7-0 double-armed silk corneal suture with atraumatic needles, the continuous corneal suture of Castroviejo is then inserted, placing all the bites 1 mm. from the fluorescein-stained incision (fig. 4).

It is our practice to begin the first bite at the 9-o'clock position and to come out at the lower left-hand corner of the square; to begin the second bite at the upper right-hand corner of the square and to come out at the 12-o'clock position; to begin the third bite at the 6-o'clock position and to come out at the lower right-hand corner; to begin the fourth bite at the upper left-hand corner and to come out at the 9-o'clock position. The last bite begins at about the 3-o'clock position and comes out about 3 mm. from the limbus. As each bite is placed, the loop of suture so formed is placed beyond the upper left corner of the square. Each succeeding loop is placed on top of the preceding one. One end of the suture is then cut off, and a bite is placed in the middle of the square. The two ends of this last suture are then fastened in a mosquito clamp.

A keratome incision is then made in the lower right-hand corner of the square, beveling it in the manner described by Castroviejo and Thomas. Care must be exercised in this maneuver to avoid injuring the lens. By making this incision in the corner of the square, only one cut is left on that leg of the square to be done with scissors. As soon as the anterior

ner. Finally, the upper end is finished in the same manner. While the assistant continuously drops citrate solution over the operative field, a similar graft is excised from the donor eye, using the same procedure, except that no Moss suture is used, and the instruments are not tilted when cutting.

The graft is then picked up with the

Fig. 4 (Stansbury and Wadsworth). Steps in placing the suture in the cornea, with arrangement of the loops.

chamber is opened, the assistant begins instilling 1-percent sodium-citrate solution into the conjunctival sac (to avoid formation of fibrin). While the square is lifted a slight distance above the lens with the mosquito clamp attached to the Moss suture, the lower blade of the de Wecker scissors, tilted in the same manner as was the keratome, is then passed through the keratome incision and the remainder of the lower leg of the square is completed. The scissors are turned and the left hand side of the square is cut. The scissors are then brought down to the lower right-hand corner of the window, and the right-hand side is completed in the same man-

spatula and gently placed in the window in the recipient's cornea. Any rolling of the edges or corners is corrected with the spatula. Then the suture is tightened, using the small straight and the small curved utility forceps. We begin to tighten with the last suture inserted and work backwards to the first one (fig. 5). When all the sutures are snug, and the graft is in good position, a surgeon's knot is tied at the 3-o'clock position, near the limbus. The instillation of the citrate solution is then stopped, and a drop of 3-percent atropine solution is instilled. At this point, we inject a small amount of adrenalin solution (1:1,000) subconjunc-

tively. Three through-and-through lid sutures are then put in position—one in the center of the lids, and one 3 to 4 mm. to each side. Before the last suture is tied, penicillin ophthalmic ointment is injected into the conjunctival sac.

When the rabbit is taken back to his quarters, a meshed-wire floor is placed in his cage instead of straw. Every other day, postoperatively, 1-percent atropine

DISCUSSION

ANESTHESIA

Probably no one factor has given us more concern than the administration of the anesthesia. The first system tried was to calculate the amount of pentobarbital to be given and to make a slow intravenous injection of this amount. Many rabbits will go into respiratory failure

Fig. 5 (Stansbury and Wadsworth). Final steps in completion of the suture.

ointment and penicillin ophthalmic ointment are instilled into the conjunctival sac. One week after operation, the animal is again given the sodium-pentobarbital anesthesia, and the sutures are removed. If anterior synechiae are present, they are broken up with adrenalin subconjunctivally, or neosynephrin or atropine in the conjunctival sac. If infection is present, penicillin is used as long as necessary. It is desirable to keep the rabbit 6 to 8 months postoperatively to determine whether or not the graft will remain transparent.

within 15 minutes if this is done. Once administered, there is practically nothing the operator can do to lighten the effects of the anesthetic. Nonvolatility is one of the characteristics of the barbiturates that makes for a prolonged and continuous anesthesia. This same nonvolatility precludes their excretion through the lungs, and so the concentration depends solely on the dosage. Once too much is given, we have been unable to resuscitate the rabbit. Since this was the case, we tried to weigh the rabbit more carefully and to calculate the dosage more accurately. The

response to pentobarbital is quite variable in different rabbits, however, as it is in human beings. Large rabbits may die with less than the calculated dosage, and small ones may require double the estimated amount.

The attempt was made to give the anesthetic intraperitoneally, but here the absorption was very slow and irregular. Large amounts are required for deep anesthesia, and the large number of doses and the amount of time required to watch the animals precluded this method. A weaker solution of sodium pentobarbital was tried, but this was not found to be satisfactory.

Finally, fractionalization of the anesthesia was worked out, and this system has proved satisfactory. Three fourths of the estimated dosage is slowly given in an ear vein $1\frac{1}{2}$ hours before operation. One hour later, if the rabbit is not too sluggish, the rest of the dose is given. Just before fastening the animal in the clamp, additional pentobarbital is given as needed. This method of fractionalization of the administration of the anesthesia has resulted in no deaths.

SEPARATION OF THE LIDS

Wide separation of the eyelids, without the interference of cumbersome instruments, is necessary during the operation: (1) to provide an operative field, and (2) to prevent pressure on the globe. In the rabbit we have tried three methods of holding the lids apart: (1) the conventional speculum, (2) sutures through the lids, and (3) Castroviejo mosquito lid-clamps.

Advantages of the speculum are ease and quickness of insertion and elimination of trauma to the lids. Some workers (Castroviejo, 1941,) believe that it interferes to some slight degree with instrumentation in the operative area, especially during use of the double-bladed knife,

and that it does not provide as large an exposure as the other two methods.

Lid sutures provide a satisfactory operative field and are particularly efficacious in immobilizing the nictitating membrane. However, their disadvantages are considerable. They are painful and often arouse the rabbit. They may cause hematomas of the lids. They often result in bleeding, and blood in the conjunctival sac, postoperatively, is undesirable because it forms an excellent medium for bacterial growth.

Castroviejo's lid clamps also provide a good field and do not have the disadvantages of the lid sutures. Nevertheless, the small drape used in rabbit surgery does not constitute a good anchor. Lid sutures and lid clamp may produce too much traction and may cause tenting of the lids, which will result in poor exposure.

After trying the second and third methods on a number of rabbits, the first method—the use of the lid speculum—was adopted as the least traumatic and the most facile procedure. It is comparatively easy to avoid touching the speculum with any of the cutting instruments simply by rotating the globe with the fixation forceps until the cornea is in the desired position. Katzin (1946) advocated complete immobilization of the globe by radial sutures in the limbus. This type of immobilization, in our opinion, is unsatisfactory, not only because its use may endanger the eye but also because it may compel the surgeon to work from awkward angles.

MARKING THE CORNEA

Correct marking of the cornea can be a great help in facilitating a successful transplant. If it is incorrectly done, however, the remainder of the procedure may be hindered by numerous unnecessary difficulties. The blades of the Castroviejo knife must be parallel and set firmly at the desired width (5 mm. for rabbits).

If the blades are not parallel, the resulting wide, ragged line will make it difficult to maintain a perfect square when the window is removed with the scissors.

The knife must be gently placed on the cornea in such a manner as to exert equal pressure on both blades; otherwise uneven lines will be made. Pressure should be sufficient to penetrate the epithelium only. If the marking is too deep, the lines tend to gape and the staining becomes diffuse. Care must be taken not to carry the lines too far along the cornea and cause unnecessary damage to the recipient epithelium. The second marking must be perpendicular to the first, or a square window will not result.

It has been our experience, as well as that of other workers (Carpenter and Smyth, 1946), that fluorescein on a rabbit's cornea will stain the entire cornea in a short time. However, we found that, by applying fluorescein to the knife and allowing it to dry before marking the cornea, the treated knife made very fine lines, which had less tendency to diffuse.

In marking the donor eye, it is advisable to hold the eye gently in order not to stretch the globe; otherwise, the transplant may be too small for the prepared area. In addition, if the eye is held too firmly, the lens will be pushed forward and its capsule will be ruptured while the transplant is being removed. Although this is not any great mishap, it adds to the difficulty of accurately cutting and removing the prepared square.

PLACING THE SUTURE

It is essential to the success of a keratoplasty that the suture holding the graft in place be located with exact precision. The suture in the corneal stroma should be approximately 1 mm. from the incision. If it is placed closer than 1 mm., it is difficult to cut the window without severing the suture. If it is placed farther

than 1 mm., it will tend to buckle the approximated edges of the cornea and the graft when the suture is tightened at the end of the operation. Furthermore, it is very important that the suture be placed so that the arms of the suture, as they crisscross over the graft, cross exactly over each corner, because these are favorite locations for bulging. That means that the suture must enter the cornea precisely opposite the apex of the right angle that forms each corner of the window. It was for this reason that Thomas gave up square transplants in favor of the circular form (Thomas, 1930).

The cornea puts up considerable resistance to the passage of the needle through its substantia propria. If the operator pulls away from the fixation forceps, the conjunctiva will not withstand the traction exerted in placing the suture but will give way at the limbus. However, if the fixation forceps are applied in such a manner that the force of the needle pushes toward the forceps, this accident will not occur.

What to do with the loops of suture while the operation is being finished is another one of the problems encountered. In order to avoid a snarl of the loops at the time when one wants to tie quickly and close the wound, it was found necessary to place the loops to one side in a definite pattern. We now lay all the loops of the suture to the upper left side, in the following manner. The first loop, which may be called the 7-to-1 loop, using the numbers as they appear on the face of the clock, is placed to the upper left, over the free end of the suture coming out at the 9-o'clock position. The second loop, called the 12-to-6 loop, is placed above the 7-to-1 loop. Likewise the third loop, the 5-to-11 loop, is placed above the 12-to-6 loop, and finally the 9-to-3 loop is placed above the other three. The free end extends off to the right (fig. 4).

Some operators place the entire suture, tighten the loops ready to tie, and then loosen the loops again, presumably to be sure the loops are located properly. This has been found unnecessary, provided the systematic steps outlined above are followed.

What should be done if a leg of the suture is cut during the operation? We have found that the corneal canals are very easy to relocate and that the needles will pass through the canals without friction; so the cut suture is pulled out and a new one inserted. If one goes too deep with the needle and perforates into the anterior chamber, the needle should be removed and a new canal made. This step is necessary to avoid formation of a fistula.

PROBLEM OF FIBRIN

The presence of fibrinogen in the normal aqueous of the rabbit results in the formation of fibrin as soon as the anterior chamber is opened, and may be a great bother in the completion of a keratoplasty. It has been our experience, as well as that of others (Thomas, 1934), that a solution of sodium citrate in normal saline will obviate the formation of fibrin.

Just as soon as the anterior chamber is opened, a continuous drip of 1-percent sodium citrate in saline should begin and be continued until the suture has been tightened and tied. If such a system is not maintained, troublesome collections of fibrin will accumulate within the window of the cornea and will render the placement of the graft more difficult. The loops of the suture must also be bathed in the citrate, or the firm snarling of the loops will endanger proper placement and lessen the chances for a satisfactory transplant. Not infrequently the coagulation may be so severe and firm that it is almost impossible to separate the sutures

from one another. The removal of the fibrin is so tedious and traumatic that the graft may be poorly placed. Soaking of the suture material in citrate before the sutures are placed in the cornea will help to maintain their pliability and softness.

TYING THE SUTURE

The mere matter of tightening the loops and tying the suture would appear very simple, but such is not always the case. If the loops are not kept in some pattern so that the operator can identify them, he will find a snarl of silk before him. However, if they are arranged as has been described, the tying can be expedited.

We use the two small forceps, one for lifting up the loop and the other for pulling it through the cornea. First we lift up the 9-to-3 loop and pull it through loosely (fig. 5), pulling on the free end of the suture near the limbus at the 3-o'clock position. Next the 5-to-11 loop is lifted up and pulled through at the 6-o'clock position. Then we lift up the 12-to-6 loop and pull it through at the 1-o'clock position. Finally, the 7-to-1 loop is lifted up and pulled through at the 9-o'clock position. The apposition of the graft is then checked all around the periphery, using the spatula for any necessary adjustments.

With the same two forceps, this procedure is now repeated and all the loops are given a final tightening. They are pulled as tight as can be done without dimpling or buckling the cornea at any place, either on the graft or on the recipient's own cornea. This is very important, because the suture controls the apposition of the cut surfaces and, if snug enough, prevents bulging. The suture is tied near the limbus, first with a surgeon's knot to hold the wet suture material and then with a conventional tie. Finally, the spatula may be inserted between the

Fig. 6. (Stansbury and Wadsworth). Pictures of rabbits after transplantation. (1), (2), and (3) show successful results. (4) is a postoperative ectasia.

center of the graft and the crossing loops of the suture and gently lifted once or twice, to give a last general distribution of the tension of the suture.

LID CLOSURE

Simple through-and-through fine black silk sutures, placed at equal intervals through the lid margins, give a very satisfactory closure of the lids. Numerous other methods were tried in an endeavor to obtain pressure, but various disadvantages precluded their adoption. Two mattress sutures were tried, but they were more traumatic and several troublesome postoperative infections resulted. Moreover, they frequently pulled through,

probably the result of the rabbit's efforts to remove the uncomfortable sutures. In an effort to maintain pressure, a wide overlapping of the lids with mattress sutures was tried, but the resulting irritation and secondary infection made this method impracticable.

POSTOPERATIVE ECTASIA

One of the difficulties we have not been able to overcome is the postoperative bulging of the central portion of the cornea, including the graft. Often, when we remove the sutures on the 7th or 8th day, we find the graft in good position, the anterior chamber reformed, no synechiae and no infection, only to be followed a

day or two later by very considerable bulging of the whole center of the cornea, with the graft at the apex of the conus. Some of these cases have progressed satisfactorily to complete healing of the scar, and the graft has remained in place and transparent for over six months (fig. 6). We attribute this type of unsuccessful result to our inability to apply a pressure bandage to the rabbit's eye. These observations make fibrin fixation of the cornea without suture (Katzin, 1946) appear a most unlikely procedure. We have been unable to prevent this condition in some rabbits, although we now remove the lid

sutures one week after operation and the corneal suture about 10 days postoperatively. We have not employed this system long enough to determine its efficacy.

CONCLUSION

A satisfactory method of keratoplasty on rabbits, following in general the technique of Castroviejo, is described. A list of the necessary equipment and a detailed description of the procedure followed are recorded. The numerous difficulties encountered, and our methods of solving these difficulties are discussed.

THE SUBSTITUTION OF CEREBROSPINAL FLUID FOR VITREOUS CLOUDED WITH OPACITIES*

MILO H. FRITZ, M.D.
New York

HISTORICAL REVIEW

"Among the most unsatisfactory cases as regards treatment and prognosis that seek advice at our various hospitals, those in which impaired vision or lost vision is due to opacities of the vitreous form a considerable number. Unless such can be traced to specific diseases, treatment is practically useless." This was said by Ford¹ 57 years ago, and the statements are as nearly true today as when they were written. Ford attempted with considerable success to clear vitreous opacities in human eyes by withdrawing 10 to 18 minims at intervals of from 2 to 3 days.

In the years intervening between 1890 and 1947, many investigators have repeated the work of Ford, although some of them had no knowledge of his work. The subject was well reviewed by zur Nedden,² in 1928 and N. L. Cutler,³ in 1937.

The first worker actually to attempt the substitution of a clear medium for vitreous clouded with opacities in human eyes was Gradenigo,⁴ who, in order to avoid loss of intraocular pressure, devised a double syringe of such construction that it delivered to a closed space containing fluid the same amount of fluid that it withdrew, thus leaving the fluid pressure unchanged. To this syringe were fixed two rubber tubes of fine caliber, leading to two sharp needles both of which were inserted into the vitreous chamber at the equator of the eye, one between the medial

and superior recti, and the other between the lateral and superior recti. In this manner, Gradenigo replaced cloudy vitreous with normal saline solution or vitreous from freshly killed animals without reduction of intraocular pressure. No clinical studies on diagnosis, amount of vitreous replaced, vision, or intraocular pressure were included in this paper.

In 1906, Deutschmann⁵ reported 67 human cases of retinal detachment treated by repeated injections of very small amounts of vitreous from calves' and rabbits' eyes. Even though the primary aim of this work was to reattach detached retinas, it is quoted as one of the earliest attempts in ophthalmology to inject foreign substances into the vitreous. Three of the cases were cured, 26 were improved, and 38 were unimproved. Deutschmann mentioned that vitreous abscess was a rare complication of this procedure.

Komoto,⁶ in 1910, reported two cases in which "good vision" was restored after the eyes had been blind for a long time following retinal hemorrhages into the vitreous. He made a scleral incision and irrigated the vitreous chamber with normal saline solution, presumably leaving a sufficient amount of saline to approximate normal intraocular volume.

Fifteen human cases of vitreous opacities caused by hemorrhages, iridocyclitis, hemophthalmos, suppurative infiltration of the vitreous, and opacities associated with detached retina treated by injection of normal saline solution were reported by Elschnig,⁷ in 1911. Vitreous (0.4 to 0.8 cc.) was withdrawn, and an equal amount of normal saline solution was substituted. All of the eyes had been blind for years. Best results were obtained in

* The expenses connected with this research were met by the Florence Ellsworth Wilson Memorial Fund Fellowship in Ophthalmology of The Eye-Bank for Sight Restoration, Inc., New York.

the cases of hemorrhage into the vitreous. Iritis and a small hypopyon complicated the recovery of one case. Poorest results were obtained in cases of opacities following iridocyclitis. Fair results were obtained in the other cases. Exact studies of vision and intraocular pressure were not made. One or two injections were made at intervals of 3 to 10 days.

In 1912, Dor⁸ reported two cases in which cloudy vitreous due to hemorrhage were treated by Elschnig's technique of withdrawing less than 1 cc. of vitreous and substituting an equal amount of normal saline solution. Vision improved from light perception to 0.4 and 0.8 in these cases.

A most interesting third case, that of a soldier who was blind following spontaneous hemorrhages into the vitreous of both eyes, was courageously reported. Two needles were plunged into the vitreous chamber. Vitreous from a horse eye, enucleated 30 minutes before, was injected. Dor concludes: "This operation was not as simple as we had hoped. The needles from which we had hoped to see blood run became clogged and while injecting a little harder in the hope of clearing the second needle, we were able to produce only a painful hypertension of the eye. The result was absolutely nil. The patient returned two years later completely blind in both eyes, and we confess with regret that we had a pronounced hypotony in the eye we had hoped to cure while the other eye had a normal tension."

In 1929, C. A. Hegner⁹ reported an experiment that attracted much less attention than it deserved. He reported replacing all the cloudy vitreous that he could withdraw from a living human eye without undue suction or other trauma with an equal amount of cerebrospinal fluid from the same patient. In the first case vision improved from light percep-

tion to 20/20 by substituting 1.5 cc. of spinal fluid. Four other cases were reported and all were similarly improved, although normal vision was not restored.

In 1946, Norman L. Cutler,¹⁰ who had previously ascertained that rabbit vitreous could successfully be transplanted from one rabbit to another, reported three human cases in which he had substituted for 1.5 to 2 cc. of cloudy vitreous equal amounts of vitreous from donor eyes enucleated immediately beforehand in operating rooms under his control. In one case, vision was improved from light projection to 20/60—1, with a correcting lens, six months after operation. The second case was a failure as far as restoration of vision was concerned, but showed that the procedure could be done with impunity under these conditions. In the third case, that of a veteran with one eye, vision was improved from 20/300 to 20/20, with a correcting lens. In all cases the intraocular pressure remained normal.

In January, 1947, after considerable experimentation on refrigerated human eyes and live rabbit eyes, I had an opportunity to use cerebrospinal fluid to replace vitreous rendered cloudy with opacities due to hemorrhage. A search of the foreign and domestic literature resulted in the brief historic review herein presented and the discovery of Hegner's great experiment.

The reviews of Duke-Elder¹¹ and Red-slob¹² revealed the tremendous amount of work that has gone into the explication of what is now known about the human vitreous, the great gaps in our knowledge of its composition, physiology, and properties, as well as the barriers in the way of further understanding.

REPORT OF CASES

The technique of the operation is still being perfected and will be described in

detail in a subsequent publication. Special needles and syringes are being developed through the kindness and generosity of Becton, Dickinson & Company of Ruthersford, New Jersey.

The indications and contradictions for this operation are still to be determined fully. At the present time, any eye with a cloudy vitreous, not in an active state of uveitis, which has not improved under the usual conservative forms of treatment in a reasonable period of time, is considered suitable for this procedure. The patients or their parents were told of the experimental nature of the operation. All had a urinalysis, complete blood count, and a Wassermann test of the blood. Foci of infection were sought for and removed.

Case 1. S. G., a 13-year-old boy, was referred by Dr. David H. Webster as a possible candidate for replacement of a completely opaque vitreous by cerebrospinal fluid. The patient had been struck accidentally over the right eye through the closed lid in January, 1946. When the swelling of the contused lids had subsided sufficiently for them to be opened, it was found that the vision had been reduced to light projection from 20/20. A regime of topical applications to the eye, rest, hot compresses, and various subcutaneous injections of unknown medications failed to make any improvement in the vision in the 12 months following the accident.

Vision in the right eye was excellent light projection. There was no red reflex. Intraocular pressure was 21 mm. Hg (Schiøtz). The pupillary reaction was normal to light. Examination of the anterior segment under the slitlamp and corneal microscope was negative. The anterior vitreous was full of tiny red-gold opacities which had the appearance of hammered copper. Findings in the left eye were entirely negative, and the vision was 20/20.

On January 14, 1947, a spinal tap was done on the patient in bed. Cerebrospinal fluid (4 cc.) was withdrawn aseptically and carried to the operating room where it was transferred to the instrument tray.

Under pentothal anesthesia, the upper nasal quadrant of the right sclera was exposed through a conjunctival incision. A purse-string suture was placed at the puncture site about 12 mm. from the limbus. The special 18-gauge needle was plunged into the vitreous chamber and as much turbid vitreous as could be recovered by gentle suction and manipulation was withdrawn. This amounted to $1\frac{1}{4}$ cc. The globe collapsed as did the refrigerated human eyes upon which this operation had been done experimentally. Since no more vitreous could be recovered, approximately $1\frac{1}{4}$ cc. of the cerebrospinal fluid were injected. The needle point could immediately be seen clearly through the dilated pupil in the brightness of the overhead operating-room light. The purse-string suture was drawn up and tied as the needle was withdrawn and the conjunctival incision was closed. Examination with the ophthalmoscope at this point showed a clear channel in the hyaloid canal extending from the posterior lens capsule to the disc and macula, which could be seen with almost normal clarity. Dense opacities surrounded this clear channel. A 1-percent atropine-sulphate ointment and a dressing were applied to the right eye only.

The next day there was minimal conjunctival reaction and no pain or evidence of uveitis. The vision was 20/50-1, and the intraocular pressure to palpation through the closed lids appeared normal. The patient was allowed out of bed.

Three days later, the peripheral vitreous had begun to clear appreciably, tension was 19 mm. Hg (Schiøtz), and the vision was 20/40-1. On the fifth post-

operative day, the patient was permitted to go home.

Two weeks later, vision was 20/20 and the peripheral vitreous was clearer. The intraocular pressure felt normal through the closed lid, and there was no noticeable gross difference between the two eyes.

One month after the operation, vision was 20/20-1, the peripheral opacities had cleared still further, tension was 21 mm. Hg (Schiotz), and the boy and his mother were tremendously pleased.

Case 2. I. D., a man, aged 58 years, was referred by Dr. R. Townley Paton as a patient who might be benefited by this procedure. The patient had an arrested case of pulmonary tuberculosis. Between 1941 and September, 1944, he had had 11 spontaneous retinal hemorrhages into the vitreous of the left eye with recovery of useful vision after each episode except the last, which had reduced the vision to light projection. He had received tuberculin injections for 16 months prior to this because it was felt that ocular tuberculosis might have been the cause of the hemorrhages.

Vision in the right eye was 20/20, with a +0.50D. cyl. ax. 110° and a +2.50D. sph. added for work at 16 inches. The media were clear and, except for a mild sclerosis of the arteries and arteriovenous compression, the fundus was normal. Intraocular pressure was 22 mm. Hg (Schiotz).

Vision in the left eye was faulty light projection. Intraocular pressure was 19 mm. Hg (Schiotz). Examination of the anterior segment by slitlamp and corneal microscope was negative. The pupillary reaction to light was normal. The red reflex was absent. The anterior vitreous was full of strands of gray opacities.

On January 20, 1947, under pentothal anesthesia, a procedure identical to that performed on Case 1 was done, except that 1½ cc. of cloudy vitreous were aspi-

rated without undue suction or trauma. A similar amount of cerebrospinal fluid was injected, but the point of the needle could not be seen, and at the conclusion of the operation, only the inferior temporal part of the vitreous seemed clearer.

A prompt recovery from the operation occurred, but the vision did not improve. The depths of the fundus could be seen dimly. Strands of proliferative retinitis and clumped choroidal pigment could be identified. Failure of vision to improve was attributed to retinal damage caused by repeated hemorrhages. For 48 hours after the operation, the patient saw a "round spot with a hole in it" at a point in his subjective visual field antipodal to the puncture site.

The patient left the hospital on the fifth postoperative day, and when seen four weeks later, had completely recovered from the operation. The visual acuity was unchanged, but the vitreous had cleared somewhat. Intraocular pressure was 16 mm. Hg (Schiotz).

Case 3. J. C., aged 57 years, a housewife, was referred through the kindness of Dr. David H. Webster. She had had a spontaneous retinal hemorrhage into the vitreous at night, eight weeks before, and the upper half of the visual field was lost. The diagnosis lay between an inferior detachment and a neoplasm. Vision gradually deteriorated to light perception. Retinal detachment and retinal hemorrhage into the vitreous was the final diagnosis.

Vision in the right eye was light perception. The anterior segment was normal. The anterior vitreous was full of discrete, scintillating gold-brown particles. No red reflex could be obtained. The pupillary reaction to light was normal. Intraocular pressure was 11 mm. Hg (Schiotz).

Vision in the left eye was 20/400, corrected to 20/20 with a +4.00D. sph.,

with a +2.75D. sph. added for work at 16 inches. The pupillary reaction to light was normal. The anterior segment was normal to examination by slitlamp and corneal microscope. The media were clear and the fundus was normal. Intraocular tension was 16 mm. Hg (Schiøtz).

On January 25, under pentothal anesthesia, 2 cc. of cloudy vitreous were withdrawn from the right eye and an equal amount of cerebrospinal fluid was replaced. No detail of the fundus of the eye could be seen immediately postoperatively, or from that time until the day of discharge, January 30, 1947. Vision was unimproved. Tension was 11 mm. Hg (Schiøtz) in the right eye, and 16 mm. Hg in the left eye.

The right eye was quite painful for three days after operation, and even though the withdrawn fluid was felt to be vitreous, it may well have been subretinal fluid.

Case 4. M. L., aged 58 years, was a private patient operated upon by Dr. Joseph Laval, who kindly gave permission for this case report. This patient had had a spontaneous hemorrhage into the vitreous of the right eye in June, 1942. Vision was gradually recovered until it approximated normal in June, 1946, when the patient was seen by Dr. Laval. At that time the systolic blood pressure on one reading was 168 mm. Hg. The retinal arterioles were moderately narrowed with an increased light reflex, and some arteriovenous compression. Terminal twigs at the maculas were tortuous.

In August, 1946, the patient returned to Dr. Laval because of a recurrence of the retinal hemorrhage into the vitreous of the right eye two weeks previously. Vision was reduced to light projection. Tension in both eyes was 20 mm. Hg (Schiøtz). Corrected vision in the left eye was 20/20. In the affected eye, the anterior segment was normal. The pupil-

lary response to light was normal. The anterior vitreous was full of strings of reddish, granular opacities.

At operation, under local anesthesia, done in the inferior nasal quadrant, 1¾ cc. of stringy black vitreous fluid were aspirated, and fresh blood appeared in the syringe at the end of the aspiration. An equal amount of cerebrospinal fluid was injected, but the needle could not be seen in the vitreous chamber and the reflex appeared black on immediate postoperative examination. There was no improvement for the remaining five days of hospitalization. There was no change in tension. Recovery from the operation was uneventful. No cause for failure can be ascertained so soon after operation.

SUMMARY AND CONCLUSIONS

That the substitution of cerebrospinal fluid for cloudy vitreous is practical has been established. Four patients on whom this operation was performed are reported. The youngest patient, aged 13 years, whose vitreous hemorrhage followed trauma, presented the most remarkable case in that one year after an ocular contusion, vision was improved from light projection to 20/20-1. The three other patients, whose ages were in the late fifties and who had had spontaneous retinal hemorrhages into the vitreous, showed no improvement in vision following this procedure. From these experiments, admittedly inconclusive because of the short period of postoperative observation, it is felt that the sphere of usefulness of this operation can only be extended by the further work of many ophthalmologists. Many cases of partial or complete blindness, due to vitreous opacities, have drifted away from proper ophthalmic care because of the discouraging results of more conservative treatments.

SODIUM SULFACETIMIDE*

ITS USE IN TREATMENT OF CERTAIN DISEASES OF THE EYE

WILLIAM L. BENEDICT, M.D., AND JOHN W. HENDERSON, M.D.
Rochester, Minnesota

In the search for a sulfonamide that was efficacious when applied locally for treatment of infections, Robson and Tebrich,¹ and Robson and Scott,²⁻⁵ all of Scotland, utilized the sodium salt of sulfacetimide in various concentrations in therapy of experimentally produced ulcers on the cornea of rabbits. Sodium sulfacetimide in 30-percent solution most nearly fulfilled their requirements for a drug with high solubility and adequate penetration, nonirritant effect, and a pH near the neutral point. Dickson⁶⁻⁸ followed up this experimental work by applying the drug in solutions of 10 percent and 30 percent, respectively, to injured eyes of a large number of coal miners and factory workers in Scotland. He was enthusiastic as to the results obtained with albugid soluble (sodium sulfacetimide)

and recommended its more widespread use in industry.

In the United States Kuhn,⁹ working in factories of Illinois and Indiana, used the drug extensively in the follow-up treatment of patients from whose corneas foreign bodies had been removed. By prescribing a 30-percent solution as eye drops for use every four hours, supplemented by application of the drug as an ointment at night, he was able greatly to reduce the incidence of secondary infection following extraction of a foreign body. Kuhn felt that sodium sulfacetimide was more efficacious than other drugs or methods in the treatment of traumatic corneal ulcers in the convalescent stage. To a lesser extent he utilized the drug in treatment of acute and chronic conjunctivitis.

During the past 12 months, certain patients observed in the Section on Ophthal-

* From the Section on Ophthalmology, Mayo Clinic.

mology of the Mayo Clinic were treated with sodium sulfacetimide. This drug was utilized as the therapeutic agent in approximately 65 cases. The results obtained are reported herein.

For our clinical study we employed sodium sulfacetimide (albusol soluble)* as a 30-percent solution and a 10-percent ointment for the treatment of diseases of the external part of the eye other than those associated with trauma or foreign bodies. In those cases in which sodium sulfacetimide was administered, the treatment was not supplemented by use of any other medication. As controls, alternate patients received routine treatment. Cultures and smears to determine the conjunctival flora were not made as a routine, and no attempt was made to select patients for treatment with sodium sulfacetimide.

The drug gave best results in average cases of acute catarrhal conjunctivitis and acute conjunctivitis associated with purulent or mucopurulent discharge. We must agree with Kuhn's⁹ statement that "80% of cases were practically well within thirty-six hours if we saw them in the first twelve hours." Even those individuals who did not apply treatment within the first 12 hours of illness obtained relief from some of the symptoms of conjunctivitis. We employed either a 10-percent ointment or a 30-percent solution every two hours in the treatment of these conditions. The solution seemed to give better results than the ointment. In cases of conjunctivitis with a secondary superficial keratitis or corneal ulcer, the ointment was more soothing than the solution. In these types of disease of the eye, the results obtained by use of sodium sulfacetimide were better than those obtained by use of mercurial solutions, peni-

cillin, or other drugs of the sulfonamide group.

The results obtained in treatment of chronic types of catarrhal and follicular conjunctivitis were less startling than those obtained in treatment of acute varieties. However, the subjective alleviation of symptoms was remarkable; in fact, it was more striking than objective improvement. It was our impression that the duration of the chronic phase of conjunctivitis in cases in which sodium sulfacetimide was used was shortened as compared to that of cases in which other methods of treatment were used.

In treatment of blepharoconjunctivitis the drug was used both as a solution and an ointment; the solution was applied during waking hours and the ointment at night. Requests were received from some of the patients for an additional supply of the medicine several months after their departure from the clinic. Although this fact suggests that the patients approved use of the drug, it also indicates that the disease was still present. For the treatment of blepharoconjunctivitis, we do not feel that methods in which this drug is employed are superior to others but that the drug should be accepted as one, among others, that gives reasonably good results.

We employed sodium sulfacetimide in some cases of keratitis sicca complicated by secondary conjunctivitis. The drug promptly alleviated the conjunctivitis and brought patients a great deal of relief during the phase when artificial-tear solutions alone were inadequate.

In treatment of angular conjunctivitis, we did not find the drug superior to the usual preparations of zinc. In cases of vernal conjunctivitis and primary keratitis uncomplicated by conjunctivitis or corneal ulcer, the drug seemed to have no effect. There was no opportunity to test the effect of locally-applied sodium sulfacetimide on trachoma.

* The drug for this clinical survey was kindly furnished by Schering Corporation.

Sodium sulfacetimide was used successfully as a collyrium in some cases in which other drugs had produced dermatitis of the eyelids. Sensitivity to sodium sulfacetimide developed in one case; in practically all cases, however, the patients used a 30-percent solution with little complaint. In many instances a 30-percent solution was said to produce a burning sensation momentarily. Because of the high concentration of the drug in solution, a fine white precipitate usually appears on the cap of the dropper bottle and on the eyelashes. The patients always were warned of the tendency of this drug to precipitate.

The work of Kuhn, Dickson, and others would seem to indicate that sodium sulfacetimide should be used more widely

than it is now for treatment of posttraumatic corneal ulcers occurring among industrial workers. Our experience with the drug indicates that it is safe and efficacious for routine use in many types of conjunctivitis occurring in patients seen in private practice.

CONCLUSION

A drug, sodium sulfacetimide (Schering Corporation), prepared as a 30-percent solution and a 10-percent ointment, was utilized in the treatment of certain diseases of the external part of the eye during the past year. The drug was found safe for average clinical use and seemed most efficacious for treatment of acute varieties of catarrhal and purulent conjunctivitis.

ANTITOXIN TREATMENT OF STAPHYLOCOCCIC CORNEAL ULCERATION*

JAMES H. ALLEN, M.D.
Iowa City, Iowa

Corneal lesions occurring in the course of staphylococcic blepharoconjunctivitis are of two varieties. One, superficial punctate epithelial keratitis, is frequently encountered during acute exacerbations of the conjunctival lesion. With adequate treatment of the conjunctivitis, the keratitis subsides without sequelae. The second and more serious corneal complication also occurs during an acute exacerbation of the conjunctivitis. It is characterized by the development of marginal corneal ulceration with underlying stromal infiltration, accompanied by iritis (figs. 1, 2, and 3) and unless brought under control may progress to the development of a ring ulcer of the cornea. This course was observed in one case resulting in loss of the globe and in stimulating a search for better treatment.

The logical therapeutic agent seemed to be antitoxin since corneal lesions had been produced experimentally by the instillation of staphylococcus toxin¹ onto the cornea. Therefore, 25 patients, all of the cases seen in the eye clinic between September, 1937, and September, 1940, with staphylococcic blepharoconjunctivitis and marginal corneal ulceration, were treated with antitoxin. The only additional treatment was the instillation of 0.2-percent aqueous solution of scopolamine hydrobromide onto the cornea to relieve photophobia.

After the etiologic diagnosis had been

established, antitoxin was administered by daily intramuscular injections of 10,000 units. A total of 40,000 units was given to 22 patients; 50,000 units to one patient; 60,000 to one and 80,000 to another (tables 1, 2, and 3).

All of the patients in the series had blepharoconjunctivitis of both eyes; 11 had superficial punctate epithelial keratitis of one cornea and marginal ulceration with stromal infiltration in the other; the remaining 14 had the more severe corneal lesions in each eye. Little change was observed 24 hours after the first injection of antitoxin. However, definite improvement occurred within 48 hours. Conjunctival discharge and congestion diminished; superficial punctate epithelial lesions of the cornea decreased in number; and the corneal ulcers and infiltrations became smaller. Thereafter, improvement continued slowly in several cases and rapidly in a few. The majority of the corneal ulcers healed and the infiltrations disappeared in 5 to 7 days after the first injection of antitoxin (figs. 3 and 4). In three cases, healing occurred in three days; whereas, in two cases the lesions persisted for 10 days (see tables). Although superficial corneal scarring remained at the site of the ulcers, it was marginal and did not result in the loss of visual acuity in any patient.

In addition to the ocular lesions, one patient had an extensive sycosis vulgaris; two had an acneform eruption of the skin; and one had impetiginous lesions of the face. All of these manifestations regressed simultaneously with the improvement of the ocular lesions.

Before treatment, sensitivity tests were

made on each patient by injecting 0.1 cc. of horse serum intradermally into one forearm and 0.1 cc. of the antitoxin intradermally into the other forearm. Although no hypersensitivity was revealed, 5 of the 25 patients developed serum reactions. The first and second patients

developed severe serum sickness with high fever, lymphadenopathy, generalized aches and pains, stiffness of the joints, and rash over the abdomen, chest, and neck. These reactions subsided without sequelae. Three other patients had mild transitory reactions. One noticed hives

in the region of the injections on the hips and at the sites of the skin tests on the arms four days after the first injection of antitoxin. The other two developed pain and stiffness of the joints associated with moderate elevation of temperature for one day on the 7th and 8th days after the first treatment.

Bacteriologic studies including aerobic and anaerobic cultures, scrapings, and secretion smears were made on these patients before, during, and after antitoxin treatment. Only staphylococci and occasionally *Corynebacteria xerosis* were found. In 23 cases the staphylococci were aureus and in two, albus. All strains

were hemolytic, fermented mannitol, and produced potent exotoxin. During and after treatment with antitoxin, there was no apparent reduction in the number of staphylococci.

lished after the corneal lesions healed. In 22. patients; the remaining conjunctival lesions slowly regressed. In one patient, a slight superficial punctate epithelial keratitis appeared 24 hours after the first

* ULCER OF LEFT CORNEA RECURRED WITH FIRST INJECTION OF TOXOID AND BECAME SEVERE, REQUIRING FURTHER ANTITOXIN TREATMENT

Because of the persistence of exotoxin producing staphylococci upon the conjunctiva and the transitory nature of antitoxin therapy, active immunization with staphylococcus toxoid was estab-

lished after the corneal lesions healed. It was associated with an exacerbation of the conjunctivitis. However, these lesions subsided rapidly and no further recurrences developed. Another patient developed a transitory

exacerbation of conjunctivitis associated with superficial ulceration of the cornea in the site of the previous corneal lesion after each of the first five injections of toxoid. A third patient, however, had an acute recurrence of all manifestations, including marginal corneal ulceration after the first injection of toxoid. The lesions were so severe that he was given antitoxin again, and combined toxoid and

severe staphylococcic infections to prevent permanent and irreparable damage to the cornea and should be followed by active immunization, chemotherapy, or antibiotic therapy.

Since this study was made, penicillin has proved to be effective in the treatment of many staphylococcic infections. However, Thygeson² has reported that approximately 20 percent of the strains of

antitoxin treatment was continued until 140,000 units of antitoxin had been given before the exacerbations were controlled.

DISCUSSION

The rapid response of both the conjunctival and corneal lesions to the administration of antitoxin furnishes clinical proof for the theory that toxin is an important factor in the production of staphylococcic conjunctivitis and corneal ulceration. The recurrence of superficial epithelial keratitis in two patients and severe corneal ulceration in a third, following the administration of toxoid, is further proof of the causative role of toxin.

Inasmuch as antitoxin therapy is transitory, it is of practical value only in

staphylococci isolated from the eye are resistant to penicillin. Therefore, antitoxin therapy should be useful in severe infections caused by penicillin-resistant strains of staphylococci.

SUMMARY

The acute manifestations of staphylococcic blepharoconjunctivitis complicated by corneal lesions subsided under antitoxin treatment in a series of 25 patients. Minor corneal lesions recurred in two cases, and severe corneal ulceration reappeared in one case immediately following the institution of toxoid therapy. Serum reactions occurred in 5 of the 25 patients even though skin tests failed to reveal hypersensitivity.

CONCLUSIONS

Both the response to antitoxin therapy and the relapses following the institution of toxoid therapy furnish clinical proof for the theory that toxin is an important factor in causing the acute lesions in staphylococcic ocular infections.

Antitoxin is of practical value as a temporary measure in the treatment of severe staphylococcic infections until active immunization, chemotherapy, or antibiotic therapy can become effective.

MEDICAL ASSISTANCE AT PROFESSIONAL LEVEL*

PARKER HEATH, M.D.[†]

Boston, Massachusetts

Resultant of multiple factors, there is a shortage of physicians, and this shortage will continue for some years. How to extend medical care has, therefore, become the concern of many well-meaning people. The problem of more and better distribution of medical care is not likely to be met by any of the conventional measures and methods now in sight.

Lay interest has been and is largely political. Up to this time, it fails to tie threatened government aggressions with responsibility. The profession itself is taking various measures to overcome the shortage of physicians and their services. Among these measures are larger classes at undergraduate level, an increase in the number of residents and internes, provision for more fellowships, refresher courses, and basic-training programs in the specialties. Constantly improving methods of treatment and prevention of

disease, the aftermaths of research and education, also give more, as well as better, medical care. Furthermore, medicine has trained certain lay people to care for the sick. Within this classification is the nurse; for the function of the nurse, when trained by medicine and practicing under its laws, is to care for the sick. Laboratory aides, X-ray technicians, office workers, and special workers in research, all trained in medical disciplines, have greatly enlarged the extent and the effectiveness of medical practice.

Despite all the above medically trained laymen, do we in ophthalmology have sufficient technical and professional assistance? Ophthalmology has not seriously gone into the problem of training high-level assistants except in orthoptics. The orthoptic technicians are excellent as far as they go, but they have a narrow range. Their opportunities for assistance are too limited, and the supply is restricted because recognized training centers are too few. Yet, ophthalmology in its various segments probably more than any other specialty is adaptable to professional assistance. Although both the already numerous methods of examination and the complications of instruments are increasing,

*From the Department of Ophthalmology, Wayne University College of Medicine, Detroit, Michigan. Read at the 82nd annual meeting of the American Ophthalmological Society at San Francisco, California, June, 1946.

[†]As of July 1, 1947, pathologist at the Massachusetts Eye and Ear Infirmary and clinical professor in the Department of Ophthalmology at Harvard Medical School.

no serious effort has been made to train a professional personnel, with the exception of orthoptics.

The obvious question arises—is it desirable to create such a group of medical assistants? Medicine has always been reluctant to teach lay people in the field of practice. This wariness is simply a protection to the public and aims to avoid increased health problems from low standards and quackery, for there have always been those at the fringe of Medicine who see many people.

For 2,500 years, an item in our code has been and now is to teach only those who follow and are controlled by the laws of Medicine. The current procedure of those groups operating on the fringe of Medicine is to write their own rules for their own advantage and economic administration. Using medical symbols, they continually press for more and more legal recognition, so that legal acceptance has come to possess but little professional merit in problems of health.

Schools, the military, industry, and civic organizations are badgered by these activities. The principles and the practice of caring for the sick are not, however, subject to short cuts in education or ethics. To achieve medical acceptance and to merit medical instruction and teaching, a lay group must accept and work within the laws of Medicine. The nurse has achieved this recognition.

A consistent and common pedagogic function of the physician is to train lay assistants by preceptorships. These persons, bound to the principles of Medicine by the physician's high standards and disciplines, greatly extend the range of his practice and reduce the onus of his daily grind. The overall effect is to extend high-level services over a larger number of patients. The gathering of data relating to the ocular health of an individual is sometimes a long and laborious

process. Consequently, a medically educated and accredited personnel, trained to assist in this work, will extend the ophthalmologist's service and ease the burden of his practice.

What should be the educational scope of these assistants? The answer to this question has direct bearing on the possible contacts they may have with the overall practice of the ophthalmologists. While doubtless there would not be complete agreement as to which parts of the examination could be conducted by assistants, some ophthalmologists would assign one part and some others, still the following parts of an eye service may be listed as suitable for assignment to medical assistants at a professional level.

Refraction. Instillation of drops, shadow and subjective tests, not the history, muscle balance, tonometry, external and ophthalmoscopic examination, and prescription.

External diseases. Smears and cultures, some forms of therapy under supervision, photography if indicated.

Perimetry. Visual fields and scotometry.

Tonometry. Under supervision.

Orthoptics. The conduct of fusion training.

Ophthalmoscopy. Assistance in photography when indicated, note taking.

Biomicroscopy. Assistance in placing the patient, drawings and notes.

Gonioscopy. Assistance in placing the patient, drawings and notes.

Ocular Motility. Assistance in plotting and recording fields, and note taking.

Screening tests. In schools and industry.

Surgical. The care and preparation of instruments, assistance during the operation.

First Aid. In industry and schools.

Laboratory. Smears and cultures, tis-

sue sectioning, chemistry data recording, preparation of drugs and solutions.

Contact Glasses. Assistance in refraction and fitting of trial shells and molds.

Library. Collection of abstracts and references, assistance in preparation of papers.

Nursing Care. On occasion.

In practice most of us delegate parts of the examinations to trained personnel. This assistance is trained by the preceptor method—a method which requires many years and does not turn out enough well-rounded, trained people to meet the demands or the possibilities. From the experimental point of view, the preceptor-trained associate is a success. To increase their numbers, approved academic channels may be used. The admittance standards to the course of study leading to an ophthalmic associationship would be those of college entrance, plus aptitude. The suggested curriculum would run four years at college level and lead to a bachelor's degree. About half of the subject matter would be in the field of the humanities and would be taught by the literary and science faculties. History, English, and languages, biologic and social sciences would be conventionally proportioned. The last two years would be chiefly concerned with technical training and would be the responsibility of the medical teaching staff.

A technical curriculum is suggested in this outline of subjects and hours for the Junior and Senior years.

<i>Subject</i>	<i>Hours</i>
(Lecture & Laboratory)	

FIRST SEMESTER—JUNIOR YEAR

Anatomy—gross, head, neck, dissections. Includes comparative and embryology	240
Neuroanatomy	88
Bacteriology	72
Physiologic Chemistry	216
Histology of the Eye	144

SECOND SEMESTER—JUNIOR YEAR

Psychiatry and Neurology	72
Physiology	216
Physiologic Optics	72
Pathology	216
Use of Medical Library	2

FIRST SEMESTER—SENIOR YEAR

Refraction	288
Ocular Muscles	72
Orthoptics	140
Optical Manufacture	100
Contact Lens	20
Perimetry	200

SECOND SEMESTER—SENIOR YEAR

Biomicroscopy	12
Refraction	288
Tonometry	4
Orthoptics	140
Screening Methods	100
Nursing—Ophthalmic	50
Surgical Equipment	100
Medical Illustration	100
Office Practice	50
Statistics	10

CONCLUSIONS

The development of a professional group of ophthalmic associates will make a substantial contribution to medical care in our specialty. It can be created within existing educational facilities. The suggested program would run four years at college level and lead to a bachelor's degree. About half of the subject matter lies in the field of the humanities and would be taught by the literary and science faculties. The remainder is largely technical and is the responsibility of the medical teachers. The admittance standards would be those of college level plus aptitude. On successfully completing this course, the rewards to the associate and his acceptance by medicine should be consistent with his training, ability, and responsibilities. If the formation of this group within our field has survival value, it will be because it extends medical service and is better for the patient.

243 Charles Street (14).

THE USE OF FURMETHIDE IN COMPARISON WITH PILOCARPINE AND ESERINE FOR THE TREATMENT OF GLAUCOMA*

ELLA UHLER OWENS, M.D., AND ALAN C. WOODS, M.D.
Baltimore, Maryland

The results of the use of furmethide (furfuryl trimethyl ammonium iodide) in the treatment of glaucoma have been reported in two previous papers.^{1,2} When these papers were published, furmethide was available only in small quantities, but it now appears that the drug will become available commercially. The purpose of this paper is to compare furmethide with the conventional drugs, pilocarpine and eserine, in the treatment of primary glaucoma.

The results in a group of 60 cases of primary glaucoma treated with pilocarpine and eserine were compared with the results in a group of 65 similar cases treated with furmethide. The ocular tension in all cases of both groups exceeded 40 mm. Hg (Schiotz) before therapy. Cases of both congestive and noncongestive glaucoma were included in both groups. All of the patients were admitted to the hospital.

METHODS OF TREATMENT

The methods of treatment in the pilocarpine and eserine group were not as uniform as in the furmethide group. In the latter, all patients received one drop of a 10-percent solution of furmethide instilled into the conjunctival sac every 15 minutes for 2 hours, then every 3 hours until the tension had been reduced to normal, or until an operation had been performed. The methods of treatment in the pilocarpine and eserine group may be summarized as follows:

Pilocarpine (2-percent solution). 22 cases. Usually given every 2 hours; occasionally every hour or every 3 hours; rarely every 30 minutes for 4 doses, then every 3 hours.

Pilocarpine (1-percent solution). 7 cases. Usually given every 2 hours or every 3 hours; rarely every hour.

Pilocarpine and Eserine. 24 cases. Usually pilocarpine (2-percent solution), occasionally pilocarpine (1-percent or 5-percent solution) alternating with eserine (0.25-percent solution) every 2 hours; occasionally pilocarpine (2-percent solution) and eserine (0.25-percent solution) every 15 minutes for 1 hour, then every 2 or 3 hours.

Eserine. 7 cases. Usually eserine (0.25-percent solution), rarely eserine (0.50-percent or 1-percent solution) every 15 minutes for 1 hour, then every 3 hours.

RESULTS

The results are summarized in Table 1.

1. In the pilocarpine and eserine group (60 cases) the tension was reduced to 35 mm. Hg (Schiotz) or less in 53 percent of the cases as compared with a similar reduction of tension in 77 percent of the cases treated with furmethide. This is statistically significant ($t = 2.9$).

2. Tension before therapy was over 55 mm. in 47 percent of the patients in the pilocarpine and eserine group. In the furmethide group, however, the initial tension was over 55 mm. in 62 percent of the patients. Thus furmethide was used in a group with higher initial tensions.

Comparison of the figures in Table 1 shows that furmethide was more effective than pilocarpine and eserine in treating

*From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University.

cases with initial tensions over 55 mm. ($r = 2.7$). It also appears to be more effective in treating patients with initial tensions less than 55 mm., although the results are not quite statistically significant ($r = 1.5$).

glaucoma whose tension had been uncontrolled by pilocarpine. The group included cases of congestive and noncongestive glaucoma. Before furmethide therapy was started the tension had been consistently elevated, varying from 30 to

TABLE 1

COMPARISON OF THE FAVORABLE EFFECT OF TREATMENT WITH FURMETHIDE AND WITH
PILOCARPINE AND ESERINE ON VARIOUS STAGES OF PRIMARY GLAUCOMA:
PERCENTAGE REDUCTION OF TENSION TO 35 MM. OR LESS

Treatment	Initial* Tension over 55 mm. Percent	Initial Tension under 55 mm. Percent	Late Cases Percent	Early Cases Percent	Total* Percent
Furmethide	75	80	67	79	77
Pilocarpine and Eserine Group	43	63	52	57	53

* Statistically significant difference in percentage.

3. Early and late glaucoma. The patients were divided into two groups, those with so-called early and late glaucoma. Cases of early glaucoma were considered to be those in which the field defect was less than 30 degrees in any meridian and the blind spot not enlarged more than 10 degrees in any diameter. According to this classification, 65 percent of the cases in the pilocarpine and eserine group had late glaucoma. In the furmethide group 70 percent of the cases had late glaucoma.

The table shows that furmethide was more effective than pilocarpine and eserine in treating both early and late cases, although the differences are not quite statistically significant: ($r = 1.4$) in the early cases, ($r = 1.5$) in the late cases.

COMMENT

Furmethide was also used in a separate group of 20 outpatients with primary

40 mm. Hg (Schiotz). In half of these patients the tension was reduced to normal (25 mm. or less) by furmethide given in 10-percent solution from 3 to 6 times a day. As previously reported, these figures show that furmethide is effective in controlling the tension in certain cases where pilocarpine has failed.

CONCLUSIONS

1. Furmethide is more effective than pilocarpine and eserine in the treatment of cases of primary glaucoma in which the tension before therapy exceeds 40 mm. Hg (Schiotz). It is especially valuable in cases in which the initial tension exceeds 55 mm. Hg (Schiotz).

2. Furmethide is effective in certain cases of primary glaucoma in the lower tension groups in which treatment with pilocarpine has failed.

CEPHALOSPORIUM KERATITIS*

ARTHUR J. BEDELL, M.D.

Albany, New York

"Fundus infections are of such common occurrence that we have found it necessary to consider mycotic disease in the differential diagnosis of practically every obscure infection." With these words the authors of the *Manual of Clinical Mycology*¹ preface their excellent presentation.

Ophthalmologists have, as usual, been alert and able to suggest the methods of examination to prove the diagnosis of several of the mycoses such as the rare sporotrichosis and the common blastomycosis.

The physicians of the United States are now more fungus conscious than ever before, not only because more cases have been seen, but also because they are apprehensive that when the infected return from the Pacific they may spread the disease. So far this fear has not been justified.

Serra,² in 1929, reported the first case of ocular cephalosporium, a keratitis. He carried his cultural examination to a logical and exact termination. Maffei³ confirmed Serra's observations and extended their scope.

Correlated and suggestive studies have been recorded by Morax⁴ of a corneal ulcer with hypopyon caused by the verticillium graphii, and by McKee⁵ in blastomycosis. An interesting citation of corneal involvement, caused by glenosporea graphii, somewhat similar to the cephalosporium, was made by R. E. Wright.⁶ The corneal slough was tough, with a slightly undermined edge and a grayish-yellow, tightly adherent central mass. Lundsgaard⁷ reported a hypopyon

keratitis with a mould and Stoewer⁸ experimented with moulds in rabbits' eyes.

When, in 1932, Miller and Morrow⁹ wrote about cephalosporiosis, they found only five cases in the literature, three gummalike and two superficial skin. Hartmann¹⁰ called attention to the association of cephalosporium and trichophyton gypseum.

Other observers including Lewis and Hopper,¹¹ Grutz,¹² Boucher,¹³ Benedek,¹⁴ Cabrini and Redaelli,¹⁵ Leao and Lobo,¹⁶ Klebahn,¹⁷ and Beym¹⁸ have had clinical and laboratory experience with the various types of cephalosporium.

The most complete presentation is by Dodge.¹⁹ Other recommended sources of information on the mycoses are the works of Ash and Spitz²⁰ and the *Manual of Clinical Mycology*¹ under the authorship of Conant, Martin, Smith, Baker, and Callaway.

CASE REPORT

A 41-year-old, rugged farmer was examined 10 days after his left eye had been injured when struck by a cow's tail. The cow was healthy and the accident such a common one that no attention was paid to it until the day before he was first seen when the eye became painful, red, and sensitive to light.

The right eye was negative externally. Vision in this eye was: 6/15 +2.50 6/5. Vision in the left eye was 6/15. The lids were red and swollen and the entire bulbar and palpebral conjunctiva was congested. The injection was greatest in the lower cul-de-sac and on the proximate globe. The cornea was clear, except in the lower outer quadrant where a 3-mm. gray ulcer with a soft, ill-defined margin was close to the limbus. The iris was congested, the

*Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

Fig. 1 (Bedell). Yellow-white corneal ulcer with a furred margin; hypopyon, ciliary congestion.

pupil measured 2.5 mm. and responded actively to light, although it only dilated to 4 mm. after the instillation of atropine. The aqueous was cloudy but there was no hypopyon.

Three drops of the aqueous solution of 5-percent sodium sulfathiazole were instilled into the lower cul-de-sac every two hours. After three days, the ulcer was unchanged. The entire area was then treated with tincture of iodine without any improvement. Penicillin (2,500 units to 1 gm. of white ointment) was put into the eye every hour, and under this treatment the infiltration increased.

The 3-mm. corneal ulcer was covered by a yellow-white, slightly wrinkled plaque. The peripheral portions were thickest and seemed to furl away from

Fig. 2 (Bedell). Five days later. Marked improvement. Ulcer less yellow, more circumscribed, hypopyon decreased.

the uninvolved surrounding cornea. There was a 2-mm. hypopyon, and the bulbar congestion continued to be greatest below. The culture yielded staphylococcus albus and a few Gram-positive cocci. The appearance of the ulcer was so suggestive of a mould growth that, although previous attempts to cultivate one had failed, potassium iodide was given internally.

Five days later, the improvement was sufficient to confirm clinically the diagnosis of mould. The ulcer was not only softer and more yellow, but was also markedly reduced in surface and depth. It was less than one half its former size and the hypopyon was about one quarter as large as formerly. The patient was taking 15 gr. of potassium iodide, three

Fig. 3 (Bedell). Ulcer healed, thin scar, pupil dilated.

times a day. The cultures which proved the diagnosis were taken at this time.

Three days later there was no hypopyon and the corneal area was gray and slightly depressed.

When seen nine days later, the globe was whitening and the corneal facet had a smooth, light-reflecting base.

The improvement continued. When last examined, uncorrected vision was 6/12; and corrected vision was 6/6, with a +2.00D. sph. \ominus +50D. cyl. ax. 180°. The corneal surface was smooth, and only a nebulous, round, superficial scar remained. The pupil was slightly irregular

with a fine arc of uveal pigment on the lens capsule.

LABORATORY REPORT

The report from the Albany Hospital and the Albany Medical College Laboratory by Dr. William Kaufman was:

"Cultures were taken on December 22, 1945. Two tubes of Sabouraud's dextrose agar and two tubes of cornmeal agar were inoculated. Growth on both media occurred after 24 to 36 hours at room-temperature incubation. Growth occurred rapidly and within five days the slants were completely overgrown. Forty-eight hours after inoculation, two Kille flasks, one containing Sabouraud's dextrose agar and the other containing cornmeal agar were inoculated with material grown on the slants. Growth occurred within 24 to 36 hours, and within one week the flasks were completely covered with the growth.

"Gross appearance of the Sabouraud-inoculated material (fig. 4): The colony is cottony and whitish with a slight pink sheen. There is a moderate amount of aerial growth.

"Gross appearance of the cornmeal-

inoculated material: The colony is grayish-white, more granular than the former, and there are few, if any, aerial hyphae. Growth shows distinct purplish pigment.

"Microscopic examination of material

Fig. 5 (Bedell). Unbranched conidiophores with many elliptical conidia.

removed from the Sabouraud medium (fig. 5): There are numerous septate hyphae containing a fair number of granules. Racquet mycelium is frequently observed. A few hyphae containing arthrospores are seen. There is an abundance of ovoid spores (conidia). These are seen to grow laterally from the hyphae in groups of one or sometimes two, and in grapelike clusters from the end of the hyphae. Many of the conidia are often elongated and a large number are seen completely round and containing what appear to be crossbars, and these bars are found centrally as well as at the end of the conidia. There is considerable variation in size of the conidia. Occasional chlamydospores are seen.

"Diagnosis: *Cephalosporium* species."

COMMENT

A corneal ulcer, the result of an abrasion caused by a cow's tail, is described.

Fig. 4 (Bedell). Cottonlike growth with a fuscous tinge, after 36 hours' incubation on Sabouraud's media.

The first laboratory report was staphylococcus albus and a few Gram-positive cocci. The usual treatment including sulfathiazole and penicillin failed to check the infection. The clinical picture was so suggestive of a mould that potassium iodide was administered and a very satisfactory regression resulted. Subsequent investigations proved that the cause was the extremely rare cephalosporium species.

This cephalosporium infection of an eye is the second on record, for after a careful research of the literature only the case of Serra seems substantiated.

The response to potassium iodide was spectacular.

CONCLUSION

Any chronic corneal ulcer with a puckered plaque should be cultured for moulds.

I am indebted to Dr. Nathan Mitchell who zealously coöperated in many experiments on the cornea of rabbits. No exact duplication of the human ulcer was obtained, although the mould-infected cornea reacted more severely than the control.

FURTHER RESEARCH ON PANNUS FOLLICULARIS TRACHOMATOSUS

C. PASCHEFF, M.D.

Sofia, Bulgaria

In former publications,¹ I have attempted to prove that pannus trachomatosis is not always a simple "keratitis vasculosa superficialis," as it has often been designated, but a *follicular hyperplasia of the corneal conjunctiva*.

Since the publication of my early discussions of this question, the existence of follicular pannus has been confirmed by other authors also.² Nevertheless, I have continued my researches on a large scale and have found follicles in many cases of pannus trachomatosis, especially in its denser formations. The last of these observations demonstrates most clearly this thesis and should be recognized by all modern trachomatologists throughout the world. Its recognition is the more important in that such cases have become very rare in Bulgaria also, just as they have disappeared from many other countries of Europe.

CASE REPORT

M. D. K., a girl aged 18 years, led by her mother because she was blind, entered the University Eye Clinic on May 20, 1939.

Four years previously her eyes had begun to water and to be red. The condition became worse, as the months passed, and her vision began to diminish. During this time she was operated on by an ophthalmologist who expressed the conjunctival granulations.

After the operation she was improved and could still see. Six months later, her vision began progressively to fail; first in the right eye, then in the left. As stated, at the time of her admission to the Clinic vision was nil.

Examination. The patient was tall and

of a weak constitution. She had suffered for some time from malaria. X-ray studies of the chest showed a tracheobronchial adenopathy with calcification of the glands of the left hilus. The Weil-Felix reaction was negative.

Blood studies gave the following results: R. B. C., 4,190,000; W. B. C. 6,500; hemoglobin, 78 percent; polymorphonuclears 60 percent (rods, 1 percent; segmented, 59 percent); lymphocytes, 34 percent; mononuclears, 4 percent; eosinophiles, 2 percent. The urine was normal.

Eye examination. A pronounced symptomatic ptosis with increased conjunctival secretion was observed. The conjunctiva of the superior tarsus was thick, rough, and toward the upper end, gelatinous in appearance. The same pathologic change was found in the lower lid also. In the plica semilunaris, the conjunctiva presented many follicles and large granulations. The scleral conjunctiva was more injected in its upper half than in the lower.

The cornea was covered with a thick, rough membrane rich in blood vessels, with fine ramifications throughout. Toward the upper limbus it was thicker and had taken on a granular aspect. Biomicroscopically, many follicles were seen. The membrane was so dense that it permitted observation of neither iris nor fundus.

Vision was perception of light.

The left eye. The condition of the conjunctiva was similar to that in the right eye; the cornea likewise was covered with a granular membrane which appeared to be thinner in the central portion. The iris could not be seen distinctly; illumination of the fundus was not successful. Vision

was equal to counting fingers at 20 cm.

Operation. The pannus of both eyes was excised with its adherent conjunctiva. Skin from the lower lid was transplanted to the right eye; mucous membrane from

Fig. 1 (Pascheff). Pannus follicularis of the right eye (low power).

the mouth to the left eye (Denig's method).

The patient left the Clinic two months later with vision sufficing only to count fingers at 20 cm. with the right eye; 6/50 with the left.

On October 9, 1939, the patient returned to the Clinic with vision in the right eye increased to 6/50; in the left eye, diminished to light perception.

Upon examining the left eye it was found that the transplanted mucous membrane was red, thick, and showed many follicles on its surface. The secretion was moderate. After some treatment the membrane was removed, and skin from the lower lid was transplanted. The patient left the Clinic on November 9th with vision equal to 6/50 with each eye.

This patient has been under constant observation for the last six years. Her vision has improved to R.E. 6/20; L.E. 6/15. The transplanted skin has become white and brilliant; the transparency of the cornea has increased considerably; neither cornea nor conjunctiva has had a recurrence of the condition. The patient is married and has healthy children.

Histology. The three biopsy specimens

were fixed in formalin, hardened in alcohol, and embedded in paraffin. The sections were variously stained: with hematoxylin and eosin, Van Gieson, Giemsa, also with other stains.

Histologic examination of the thickened portion of the biopsy specimens gave the following results: (1) pannus of the cornea of the right eye. Under low power (fig. 1) the formation of numerous grains of different size and form were seen scattered under the epithelium, which, in some places, was well preserved, in others infiltrated and even destroyed. The grains had pale centers surrounded partly by a more deeply stained cellular zone at the periphery. Between the grains the tissue was infiltrated to a greater or less degree.

Under high power (fig. 2) the grains appeared to be lymphatic follicles with germinating centers having a more or less distinct peripheral lymphocellular zone.

Fig. 2 (Pascheff). Pannus follicularis of the right eye. A follicle of the same pannus under higher power.

The cellular infiltration between these follicles consisted of many lymphocytes and plasmocytes. In the germinating centers were seen actively proliferating lymphocytes, histiocytes, endothelial cells, and many macrophages or phagocytes of

Villard. The latter were especially observable near blood vessels whose capillaries penetrated even into the germinating centers of the follicles. The latter were in different states of evolution but were for the most part individual.

(2) The pannus of the left eye (fig. 3) under low power showed the same grains in the densest part but these were of different lengths. They became fewer in number but longer. The epithelium was infiltrated in some places and had been destroyed in others. Between the follicles the tissue was moderately infiltrated. The grains had pale centers and more darkly stained peripheral cellular zones. Under higher power (fig. 4) it was seen that histologically they were *follicles with germinating centers*. In some sections the follicles were separated by connective tissue, richly infiltrated; in others, the follicles had coalesced and had formed large granulations—which I have termed *folliculoms*. Clinically the confluent follicles

Fig. 3 (Pascheff). Pannus follicularis of the left eye (low power).

resembled small sausages. The germinating centers contained the same cellular elements as those described for the right eye.

(3) The follicular mucous membrane of the transplant showed the following histologic structure: The whole membrane was richly infiltrated with numerous follicles with germinating centers as afore described. I have seen such a recur-

rence with formation of follicles in the transplanted membrane in other cases wherein the pannus had been removed

Fig. 4 (Pascheff). Pannus follicularis of the left eye. Follicles in a state of confluence (higher power).

and a transplant of mucous membrane had been made.³

DISCUSSION

This case presents the best proof available up to this time of the existence of follicular pannus. In this instance it occurred bilaterally. The follicles were observed as individual germinating centers and in coalescence. Their histologic structure and development were similar to those observed in true trachoma of the conjunctiva, although this development was independent of the rest of the conjunctiva. In fact, I have observed many cases of follicular pannus developing on the cornea when the remaining trachomatous conjunctiva had advanced to the stage of cicatrization. This individual role of the corneal limbus in chronic hyperplasia of the conjunctiva is still more strikingly apparent in vernal conjunctivitis.⁴

Follicular pannus makes it first appearance between the epithelium of the cornea and Bowman's membrane. Later it

invades and destroys the latter. If follicular pannus is removed surgically, vision returns unless there is a recurrence. To avert the latter, skin must be transplanted to the eye instead of oral mucous membrane.

As to the nature of follicular pannus, it has been shown to have a lymphoid, reficulo-endothelial structure, rich in germinating centers which, in their further development, coalesce, degenerate, and cicatrize, as in true trachoma.

In this respect, follicular pannus of true trachoma is entirely different from the fibropapillary pannus⁵ of vernal conjunctivitis and pannus lymphaticus⁶ of phlyctenular conjunctivitis. In its further stage of development it has been erroneously considered by some writers to be a granuloma of the cornea. As I have demonstrated, the latter has a different structure histologically.⁷

Finally, follicular pannus is histologically entirely different also from the granular form of lupus—keratoconjunctivitis granulosa luposa⁸—in which the whole conjunctiva of the sclera and cornea takes on a granular appearance such as is seen in conjunctivitis miliaris follicularis,³

but with these differences, it has no lymphatic follicles and the granular pannus of lupus is directly continuous with the granular conjunctiva.

In this last respect follicular pannus resembles closely the fibropapillary pannus of vernal conjunctivitis, for both begin at the limbus and generally are quite independent of the state of the scleral conjunctiva.

CONCLUSION

1. Follicular pannus is a lymphofollicular hyperplastic manifestation or reaction of the limbal corneal conjunctiva, and has the same histologic structure and evolution found in trachoma verum. 2. True trachoma, therefore, is not an exudative inflammation of the conjunctiva but a chronic lymphofollicular hyperplasia of the conjunctiva. 3. Although differing in structure, pannus follicularis calls to mind the fibropapillary reaction of the conjunctiva—pannus fibropapillaris—which today is considered an allergic reaction. 4. The best way to avoid recurrence is to transplant skin from the lid instead of mucous membrane.

THE PLACE OF PERIPHERAL FUSION IN ORTHOPTICS*

HERMANN M. BURIAN, M.D.

Boston

The division of fusion into three degrees, suggested by Worth, is generally accepted in orthoptic circles. This division may be convenient from a practical point of view, but if it is routinely and mechanically applied, it leads to blurring and oversimplification of a complex process. There is an important distinction which is not explicitly made in this division; namely, the distinction between sensory and motor fusion. To understand this distinction and the place which I believe peripheral fusional stimulation to hold in orthoptics, a word on fusion in general is necessary.

SENSORY AND MOTOR FUSION

Sensory fusion means the act of uniting into a single mental image the impressions reaching certain areas of the two retinas. Such unification takes place, in normal individuals, when corresponding retinal points or elements are stimulated. Around each corresponding retinal element, however, there is an area which, although not strictly corresponding or even frankly disparate, also permits unification of biretinal stimulations into single mental images. These areas are known as the areas of single vision of Panum. If there is within these areas a horizontal disparity between the images of the right retina and the left retina, the resulting fused image has the quality of stereopsis.

Generally speaking, then, in order to produce a single image, biretinal stimulations must fall on corresponding retinal elements or at least within Panum's areas. If they fall outside of these areas,

fusion does not occur, but diplopia results.

Motor fusion. The human organism has a pronounced aversion to diplopia—a diplopia-phobia, to use the term coined by Van der Hoeve. In order to establish single binocular vision, disparately imaged objects are brought within Panum's areas and on corresponding points by disjunctive horizontal, vertical, or torsional movements of the eyes. These movements of adjustment are the vergences or fusional movements. They represent what is called motor fusion.

The sensory unification of biretinal stimulations must be distinguished from the reflex movements which occur, when necessary, to make this unification possible. A patient's ability to perform one of these functions does not necessarily imply the presence of the other.

The sensory stimulus for the fusional movements is the disparity of the retinal images. It is as though each pair of corresponding retinal elements was the center of a field of attraction. If similar images occur at different points in this field of attraction, a relative movement of the eyes is produced which ceases when the two images overlap. The farther away from the center the image is located, the weaker is the attraction. Beyond certain limits, marked by the range of the fusional movements, the attraction ceases altogether. If the movement has taken place, then sensory fusion follows motor fusion. This is what happens under normal conditions, with people who have all three degrees of fusion.

DEGREES OF FUSION

The first degree is known as "simultaneous macular perception." A patient is

* Read before the meeting of the American Association of Orthoptic Technicians at Chicago, October 14, 1946.

said to have the first degree of fusion, if he perceives simultaneously and superimposes two nonidentical pictures presented simultaneously to the macular areas. This, evidently, is purely an act of sensory fusion.

It is supposed to be the simplest form or lowest degree of the fusion faculty, the necessary prerequisite for the second and third degrees.

Now, actually, this is by no means as simple as it sounds. To be sure, normal individuals can as a rule easily superimpose these "first-degree pictures," although they often do it more easily with pictures containing fusional stimuli. However, patients with concomitant strabismus often have great difficulties in this. They try, above all, to avoid bimacular stimulation. They will suppress, they will change the angle of squint, they will change the mode of sensory localization—all in an effort to avoid bimacular stimulation. Although they may apparently not even have the first degree of fusion, one can, nevertheless, show that some of them have a rather well-developed fusion faculty. I have seen in many instances that if the stimulation of the macular areas is avoided, such patients not only have good sensory fusion, but they even exhibit fusional movements in response to disparate stimulations. Simultaneous macular perception, then, is not necessarily the "first degree" of fusion in patients with strabismus.

Worth's second degree of fusion is present when the patient can fuse dissimilar pictures and has some degree of fusional amplitudes. This second degree is concerned both with sensory and with motor fusion. It may be present, as I have just pointed out, in patients who do not display the first degree, if there is a special distribution of the stimulus pattern. The second degree is of particular interest in the discussion of fusional

movements produced by disparate stimulation of more peripheral retinal areas.

The third degree, finally, is achieved when the patient has stereopsis. Depth perception is a sensation *sui generis* which is ordinarily based on the fusion of disparate retinal images. It has some independence from fusion, both sensory and motor, for it can occur in diplopia. Since, in my opinion, it is a fundamental sensation, it cannot be taught. It is as little a matter of experience and as little teachable as the sensation of red or green. What can be taught, is the refinement of stereopsis. Once a patient does have stereopsis, he can be trained, within limits, to discriminate ever finer differences in retinal disparities and to perceive them as depth differences.

A close analysis does not leave much to say on behalf of Worth's three degrees of fusion. The first degree is not as fundamental as appears at first glance. It may be absent in patients in whom the second degree may be shown to be present. The third degree, stereopsis, is really not the highest degree of fusion but rather a sensation *sui generis*. To be sure, it ordinarily presupposes sensory fusion as well as the presence of fusional amplitudes, but the latter in particular are accessories not essential to the sensation. Strictly speaking, therefore, stereopsis is not the highest degree of fusion.

PERIPHERAL RETINAL STIMULI

Some of the deductions which I have just presented to you are the result of studies which I undertook several years ago to investigate the part played by more peripheral areas of the retinas in the act of motor fusion.^{1, 2} These investigations were carried out by means of an instrumentation which was briefly as follows.

TECHNIQUE

The patient is seated at 15 feet from

an aluminized projection screen, with his head fixed in a headrest. Behind him are two projection lanterns placed on an adjustable stand. The beams of these lanterns are projected on the screen by adjustable mirrors. The mirrors, as well as the lanterns, pivot around a vertical axis; the projectors can be raised and lowered. Thus, they form a haploscopic arrangement, and targets projected by them can be placed independently on any desired region of the screen.

To dissociate the eyes, polaroid material is used. By placing the plane of polarization vertically in front of one eye and horizontally in front of the other eye, and by attaching corresponding sheets of polaroid material at the end of the tubes of the projection lanterns, a pretty good extinction is obtained. As a result, the targets projected by one lantern are seen only with one eye; the targets projected by the other lantern with the other eye. A third projector is used for auxiliary purposes. It, too, may be provided with polaroid. If it is desired to project a binocularly seen object, the polaroid is removed from that projector.

In order to have a check on the position of the eyes, two small movable projectors are placed one on each side of the patient. Each of these projectors also has a polaroid filter. As a rule, a short red and a short green line, each seen by one eye, are projected by these lanterns. One line is placed so that it corresponds to the fovea of the fixating eye; the position of the other line is adjusted by the patient. He keeps the two test lines always on a level or above each other by means of a handle on the projector. The position of the lines on the screen indicates directly the position of the eyes in patients with concomitant strabismus and normal correspondence. In anomalous correspondence, the position of the test lines tells the angle of anomaly.

This projection arrangement is extremely flexible. In normal individuals, it can be used to examine fusional amplitudes by stimulating any desired retinal area. Stereopsis at distance can be measured if stereoscopic slides are used in the haploscopic target projectors.

In patients with strabismus, one can measure within the limits of the screen the objective and subjective angles, if a tangent scale is projected by the auxiliary lamp. Sensory fusion in any area can be tested. Fusional amplitudes can be determined by stimulating or excluding from stimulation any desired area.

PRELIMINARY INVESTIGATIONS

In applying this instrumentation in preliminary investigations to normal individuals,¹ I found, as was to be expected, that fusional movements can be produced by disparate identical stimulations applied to the retinal periphery. I could, for example, produce typical fusional movements by presenting identical squares to the peripheries of the retinas of the dissociated eyes. These squares were at first superimposed on the screen and then slowly moved up and down, relative to each other, until the disparity of the retinal images became so large that they no longer produced an impulse to fusion. Although the observer usually saw these squares in the periphery, he was not always aware of the shapes, particularly if the squares were well out in the periphery. Their effect on the position of the eyes was determined by the test lines on which the observer concentrated his attention.

As was also to be expected, to obtain a standard amount of fusional amplitude the size of the stimuli had to be larger the farther away from the macula they were placed.

It was most interesting, however, to find that with targets of appropriate size

it was possible to achieve such powerful peripheral fusional stimuli that central fusion could be broken up. That is, if an observer fixated binocularly and fused a centrally seen object, it was possible to break the central fusion by strong peripheral fusional stimuli, and the binocularly seen object would appear double no matter how hard the observer tried to maintain central fusion.

STRABISMUS PATIENTS STUDIED

The examination of patients with concomitant strabismus yielded many very interesting results with regard to the visual act in strabismus.² I can mention here only those which I believe to have a direct bearing on orthoptic practice.

The patients studied had a convergent or divergent strabismus with every type of sensory reaction. The only thing which they all had in common was that the angle of squint did not exceed 12 degrees because of the physical limitations of the screen. This was no handicap, since patients with a relatively small angle of squint are the ones who are most important from the orthoptist's point of view. As a rule, larger angles have to be reduced by surgery before the patient is submitted to visual training. All patients were thoroughly tested not only with the routine methods, but also with the various tests which the projection arrangement offered.

Now, I was able to show beyond any doubt that some of these patients were able to perform fusional movements when tested in an appropriate way with the projection instrument, although there was no trace of fusional movements when the patients were examined with the routine methods. This was a significant finding, since all the best authorities had heretofore absolutely denied the existence of fusional movements in the presence of a manifest strabismus. It was

even more interesting to learn under what condition these fusional movements would come about.

I soon found in the tests preliminary to the application of disparate stimulations that two modes of response to central (macular or foveal) stimulations could be distinguished, irrespective of the state of retinal correspondence. The patients were either able to superimpose macular stimulations or they were not. For instance, if I projected a Maddox cross seen by one eye, and a movable red dot seen by the other eye, and asked the patient to move the red dot so that it would subjectively cover the zero of the scale, certain patients would place the dot without hesitation on a point on the screen corresponding to their (normal or anomalous) subjective angle and would state that the dot was now on zero. Other patients were quite unable to do this. They would move the dot until it approached the area on the screen corresponding to the visual line of the deviated eye (or the zero of the scale in anomalous correspondence). Then, suddenly, they would find that either that area of the scale or the dot had disappeared (suppression); or else the dot would suddenly jump to the other side of the scale because of a change in the sensory relation of the retinas (from anomalous to normal correspondence or *vice versa*); or, finally, the zero of the scale would keep creeping away when the dot approached, or make a slight shift to the other side of the dot, owing to changes in the angle of squint. All of these patients were unable to superimpose subjectively the dot and the zero of the scale in spite of patiently repeated attempts.

RESULTS

In this way, I could differentiate patients who presented a central sensory disturbance from those who showed no

such disturbance. It proved that these patients also behaved differently with respect to peripherally applied fusional stimulations.

Those who had no sensory disturbance did not follow peripheral fusional stimulations. When the targets were displaced vertically, either at the angle of squint or at the angle of anomaly (if the correspondence was anomalous), their eyes did not follow the disparate stimulation. They either saw the displaced targets double or, more frequently, suppressed one retinal periphery.

Those, however, who had a central sensory disturbance in the majority of the cases did follow peripheral disparate stimulations in a typical way and under one condition only—stimulation of the retinal centers had to be avoided.

The patients, with central sensory disturbance, who did not follow peripheral fusional stimulations were generally those who totally suppressed all stimulations reaching one retina; in other words, those who had complete monocular vision, as for instance in alternating divergent strabismus.

ORTHOPTIC USE OF PERIPHERAL RETINA

These results seem to me to be of considerable interest for those concerned with visual reëducation.

I believe that it is important for the orthoptist to know that peripheral fusional stimuli are very strong and capable of dominating the fusional impulses from the macular areas. By concentrating almost exclusively on central retinal areas in training binocular vision and fusional amplitudes, a powerful tool is being neglected. I am sure that in all cases favorable results could be obtained much more rapidly if use were made of the large areas of peripheral retina which are so highly responsive to disparate stimulation.

On the other hand, it is certainly significant that it is possible to diagnose, as it were, the seat of the sensory disturbance in a patient. It is not sufficient to say that a patient has or has not "first degree of fusion." The sensory behavior of the retinal periphery must also be investigated. If it is found that the patient has a marked aversion toward simultaneous stimulation of the macular areas but that he fuses with peripheral areas when the center is excluded, it would seem that the long battle between the orthoptist and the patient to establish his first degree of fusion could be won more easily and quickly by the orthoptist if she did not insist on the frontal attack on the macular areas of the patient. She should first concern herself with the peripheral areas which would more readily yield to her ministrations and should then infiltrate from there the macular areas. This should be the most effective way to overcome the sensory disturbance of the central retinal regions.

Finally, I should like to point out that there is one condition in which only peripheral retinal stimulations can be effective. This is cyclophoria. I have no personal experience with the training of cyclofusional amplitudes and do not know whether or not they can be trained. However, I do not see any theoretical reason why this should not be possible. If it is possible, it could only be achieved by stimuli placed at some distance from the retinal center. If you think of the eye as a wheel and of the visual line as a rod, the end of which is put through the center of that wheel, you will readily see how much easier it would be to turn the wheel by one of the spokes than by the rod.

CONCLUSION

If I should conclude by saying that, for all the reasons brought forth, the orthoptist should always study the sen-

sory behavior of the peripheral as well as the central areas and make use of the training potentialities of the retinal peripheries, this question is in order—what should be done about the practical application of fusional stimulations?

Unfortunately, I am not prepared to answer this question at this time. I cannot report any experiences in actual orthoptic training along the lines suggested. Conditions during the past years made it impossible to develop a method or to apply it in practice. I think that the ordinary major amblyoscopes do not offer a sufficiently large field of vision and are not flexible enough. I see no reason, however, why a simplified projection arrangement could not be developed to be used for orthoptic training of all types of disturbances.

I have found, for instance, accidentally and without looking for it, that what is known to the orthoptist as "massage" of the macula can be achieved with the projection arrangement herein described, most successfully and with very little physical effort. For this purpose the Maddox tangent scale, seen by the patient with the fixating eye, and a small colored light spot can be used. The light spot can be moved easily and with any desired speed over any area of the screen. If it is moved rapidly in the region of the visual line of the deviated eye, patients whose anomalous correspondence is not too deeply rooted will soon report that the

spot suddenly "jumped" to the other side of the screen; that is, these patients now localize according to normal correspondence.

This is only an example of how the projection arrangement can be applied. Its most important application, however, lies in the possibility of reaching, during the exercises, one retinal area while at the same time excluding others.

It should be mentioned here that even without the use of a projection arrangement, the principle of simultaneous stimulation of peripheral retinal areas can be utilized. Swan and Laughlin³ have reported encouraging results in developing single binocular vision in patients with high amblyopia ex anopsia and absolute central scotoma in the afflicted eye by using large ring targets. A green ring with a central dot for fixation was presented to the normal eye and a red ring with a blank background to the amblyopic eye. The authors state that, with training, many patients lacking sharp central vision fuse the rings and develop a considerable amplitude of fusional movements.

At present, I cannot make more definite practical suggestions, but I hope that I have indicated the important place which peripheral fusional stimulations should take in orthoptic training. I shall be much gratified if I have been able to arouse some interest in this subject.

DISCUSSION OF DR. BURIAN'S PAPER

ELSIE LAUGHLIN

Iowa City, Iowa

It is difficult to evaluate the full significance of diagnostic material such as Dr. Burian has presented, but we can appreciate the amount of study and research that made this presentation possible. I should like, at this time, to be able to present orthoptic data sufficient in quantity and quality to substantiate Dr. Burian's findings. Lacking the statistics for such a discussion, I shall begin by expressing my admiration and continue by accepting the challenge he has given us as orthoptists.

The idea of peripheral fusional training is not new at our clinic. For the past several years, we have used peripheral-fusion tactics at Iowa in an attempt to improve the chances for single binocular vision in patients with amblyopia. Recognition of the possibilities in this field of orthoptics led us to believe that we could help a number of patients with neglected monocular strabismus and offer them more than a purely cosmetic correction.

Our first observation of peripheral fusional movements was probably prompted by the considerable number of amblyopic patients who were also accommodative. This led to a more careful study of the binocular behavior of amblyopes at the synoptoscope and to the development of our simple peripheral fusion charts.

The targets consist of rings with a diameter subtending a visual angle of about five degrees. A green ring with a central dot for fixation is presented to the normal eye, while a red ring with a blank background is presented to the amblyopic eye. The ring, of course, must subtend a visual angle larger than the scotoma. These targets are used in the synoptoscope, which is adjusted by the corneal

reflex method to correspond to the deviation of the eyes. In cases where normal retinal correspondence can be demonstrated and where the deviation is not too great, the patient is instructed to carry on with similar peripheral fusion targets in the stereoscope at home. Even the small percentage of cases in which favorable results are obtained warrants the continued use of this type of fusion training. I am sorry that not enough has been done to allow a more comprehensive report. It is obvious that perseverance is difficult in these cases for the same reason that characterized their delayed initial examination. In a busy clinic, the time element involved in treating these cases orthoptically is another factor to be considered.

Returning to Dr. Burian's statement concerning the division of fusion, I admit that I have always found it difficult to classify my patients as having first, second, or third-degree fusion. I am grateful that our doctors have not insisted upon such a classification. In our clinic, we use a graphic description of the status of simultaneous perception and vergences, which is supplemented by numerous marginal qualifying notations. This seems to serve our purpose in recording initial and subsequent findings.

INFILTRATION OF MACULAR AREAS

Dr. Burian's suggestion that we infiltrate the macular areas after good peripheral fusion has been established seems logical. A method of reducing the angle of anomaly in anomalous retinal correspondence was described by Miss Walraven at the recent meeting in Boston. Starting beyond the subjective angle with one arm of the major amblyoscope sta-

tionary at zero, the opposite target is brought in repeatedly until suppression takes place, and is then moved back each time until simultaneous perception is recovered. As the targets move through the subjective angle, the patient may become aware of monocular diplopia. This diplopia is used as a tool to obtain eventual fusion at the objective angle. Is this a preliminary step in peripheral training? Miss Walraven accomplishes this with the major amblyoscope. A projection arrangement would, no doubt, have added value, if its manipulation and the gyrations of the child could be controlled as readily as is possible on the major amblyoscope.

A variation of the red-green test, somewhat similar to the projection arrangement described by Dr. Burian, is at present being used in our clinic, purely as a testing device to verify synoptoscope and after-image findings. It has possibilities as a training device when certain mechanical improvements can be made.

By inducing consciousness of the periphery, are we making an initial move toward peripheral fusional training? We use a vertical prism to displace one image to a peripheral area where it is not suppressed, thus giving a patient his first awareness of diplopia. Miss Lancaster's bar-reading technique begins by making the child aware of a double bar at a near point when fixation is on a more distant object. These images of the bar fall upon disparate retinal areas. Gradually the bar is moved toward the fixated object, thereby varying the peripheral areas brought into use. Each time suppression takes place, the process is repeated. Can

this be called infiltration of the macular areas?

As Dr. Burian points out, certain patients show a strong aversion to bimacular stimulation and are unable to superimpose dissimilar pictures (according to Worth's first-degree fusion). They often describe these targets as jumping around or over each other. We use partially identical targets (two pairs of simple 10-mm. colored balls which are fused as three balls). These targets allow for some central suppression and uncover any latent tendency toward peripheral fusion. They provide a starting point for most patients and those capable of single central binocular vision readily go on to more detailed binocular tasks. Dissimilar targets, such as the fish and the bowl, are used for testing the status of retinal correspondence in very young children at the synoptoscope.

I share Dr. Burian's opinion that stereopsis cannot be taught. Our experience seems to indicate that even in phoria cases, unless the loss of depth perception is associated with a small degree of suppression, no improvement in stereopsis follows orthoptic treatment. When suppression is present, stereopsis appears simultaneously as suppression is overcome.

Dr. Burian's extensive study of sensorial retinal relationships has made it possible for us to evaluate better the binocular behavior we encounter from day to day. I am sure he has succeeded in arousing an interest in peripheral fusional stimulations which will be manifested in future orthoptic procedures.

University Hospitals, Newton Road.

NOTES, CASES, INSTRUMENTS

WETTING AGENT FOR CONTACT LENSES

R. L. SCHMIDTKE, M.D.
St. Paul, Minnesota

Although the present day plastic contact lenses are a great improvement over both the Müller and the Zeiss glass contact lenses, there still are many problems that vex the ophthalmologist who prescribes and fits contact lenses. The most frequent complaint is fogging. The following are some of the more common causes for the fogging of vision experienced by the wearer of contact lenses: (1) Improper refractive correction. (2) Dirty contact lenses. (3) Cloudy solution. (4) Corneal edema. (5) Spasm of accommodation. (6) Clouding of the solution after insertion of lenses. (7) Meibomian-gland secretions on the anterior surface of the contact lenses. The first three causes for fogging can be eliminated by the ophthalmologist and the patient and will not be discussed here.

Corneal edema usually comes on from 30 minutes to four or more hours after the insertion of the contact lenses. It is due to the imbibition of the buffer solution by the corneal epithelium. The continued daily wearing of the contact lenses seems to toughen the corneal epithelium so that as time passes the patient can wear the contact lenses for longer and longer periods of time before fogging due to corneal edema begins. In some cases changing the strength or the formula of the buffer solutions will lengthen the time before fogging occurs.

Contact lenses, although well fitted, like any other foreign body in the conjunctival sac, induce stimuli which in turn produce undesirable reactions. Among these undesirable reactions is the spasm of accommodation noted in many cases, especially in the hyperopic patient when he first

begins wearing contact lenses. This spasm of accommodation relaxes after a longer or shorter period of time as the eye becomes accustomed to the lenses.

In the same manner the contact lens acting as a foreign body stimulates the various paraocular glands. This at first thought would seem unimportant, but if we recall that the goblet cells are most numerous in the bulbar conjunctiva and that the scleral part of the contact lens acts as a funnel placed over the bulbar conjunctiva thus catching the mucous secreted by these glands, we can readily see how the stimulation of the goblet cells will cause the buffer solution to become cloudy due to the increased quantity of mucous. This, like the spasm of accommodation, decreases in most cases as the eye becomes accustomed to the presence of the contact lens.

The greasy secretion of the meibomian glands, essential as it is in preventing the tears from spilling over onto the cheeks, and in sealing the eyelids during sleep, often proves to be the greatest problem with which the contact-lens wearer has to contend. In the first place the manipulation of the eyelids during the process of inserting the contact lenses, massages the secretion from these glands; then the contact lenses by their presence in the conjunctival sac reflexly stimulate the meibomian glands, as well as the other paraocular glands, and an excessive amount of this special sebum is produced. This increased sebum on the lid margins would be of no consequence if the anterior surface of the contact lens were wet so that it would repel the greasy meibomian-gland secretion. However, since the tears are a poor wetting agent, they do not wet the plastic contact lens. Thus, the meibomian-gland secretion is smeared onto the anterior surface of the contact lens producing a fogging of vision which is

very annoying to the contact-lens wearer.

In an effort to overcome this difficulty, patients have been instructed to place their contact lenses into one of a number of wetting agents with the hope that when the lenses are inserted the tears will wet them and prevent the smearing of meibomian-gland secretion over the anterior surface of the lenses. As wetting agents, these solutions have been very satisfactory. However, these solutions are irritating to the conjunctiva, and patients are instructed to rinse the contact lenses well with water after removing them from the wetting agent and before inserting them. By this procedure most, if not all, of the beneficial effect of the wetting agent is lost, and the patients continue to have fogging of vision due to sebum smeared over the anterior surface of the lenses.

A search has been made to find a wetting agent which would be tolerated by the conjunctiva so that some of the wetting agent might be left in contact with the lenses thus keeping the anterior surface of the contact lenses from becoming dry. To my knowledge, at the time of this writing, paratertiary-octyl-phenoxyethoxy-ethyl-dimethyl-benzyl ammonium chloride monohydrate (1:5,000) in a 2-percent boric-acid solution* is the only wetting agent that can be used without danger of producing an irritation.

The patient is instructed that when the contact lenses are removed, they are to be placed in a small, covered jar containing an ounce or so of wetting agent. The lenses should remain in this solution until the patient is ready to reinsert them. When the lenses are taken from the jar, the excess solution should be removed by a quick shake—not by rinsing. The contact lenses are inserted in the usual manner and, after the contact lenses are in place, the eyes are washed with an eyecup

filled with the wetting agent. This procedure utilizes the detergent action of the wetting agent to wash away the excess meibomian gland secretion in addition to leaving a film of wetting agent over the anterior surface of the contact lenses. This helps to keep the lenses from becoming dry and repels any remaining sebum from the anterior lens surface.

REFRACTION CLINIC*

DISCUSSION BY

ALBERT E. SLOANE, M.D.†

Boston

A man, aged 39 years, noted three weeks earlier that he saw double unless he kept his head tipped and avoided looking to the left. He had never worn glasses before, and was not greatly inconvenienced by his present difficulties. Examination revealed vision to be: O.D., +1.00D. sph. \ominus -0.50D. cyl. ax. 90°, 20/20; O.S., +1.00D. sph. \ominus -0.50D. cyl. ax. 90°, 20/20.

Distance phoria test revealed: Distance —4^A exophoria; phoria—8^A right hyperphoria (O.D.), in the primary position.

Diagnosis was paresis of the left superior rectus muscle.

DISCUSSION

The symptoms of which this patient complained could be definitely attributed to a paresis of the left superior rectus muscle. This was substantiated clinically by his tendency to keep his head cocked back and to the left so that his eyes were directed for the most part down and to the right. The red-glass diplopia field gives us some very valuable information from a therapeutic standpoint. You will

*From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.

† Director of Department of Refraction.

note that there is quite a bit of exophoria manifested in the three upward positions of gaze. This is due to an anatomic divergence produced by the axis of the orbits when the eyes are in elevation. This is not due to any muscle weakness, because if a horizontal muscle were defective the horizontal imbalance would be greatest in one of the horizontal planes. When we consider the indications for prismatic correction, the diplopia field immediately tells us how much can be accepted without disturbance. The principal positions of gaze ordinarily used by a patient are the horizontal and the lower fields, and in these areas the minimum hyperphoria is 3 arc degrees, or approximately 6 prism diopters (1 arc degree equals 2 prism diopters approximately). Therefore, a prismatic correction up to 6 prism diopters will not introduce an opposite hypertropia. You will note that in the upper right position of gaze the vertical diplopia is smaller, 2 arc degrees or 4 prism diopters, but since one can easily avoid utilizing this field, it may be omitted from our consideration.

SOLUTION

Disturbing diplopias can be relieved by several measures: 1. Occlusion of one

Fig. 1 (Sloane). Red-glass diplopia field plotted in arc degrees, x = O.D.; o = O.S.

eye. 2. Prismatic lenses. 3. Surgery.

In this instance, since the diplopia has never really been disturbing because the patient learned how to tip his head to minimize the difficulty, occlusion of one eye is not necessary. Glasses were prescribed for constant wear, which included: O.D., 2 prism diopters, base down; O.S., 2 prism diopters, base up. That is, 4 prism diopters of right hyperphoria correction were prescribed. He was told that he would still have to tip his head to neutralize the diplopia somewhat, since a partial correction only was given. It is best to prescribe, as a general rule, the smallest amount of prism that will obviate symptomatology. This has the further advantage of lasting the patient a longer time in a more suitable fashion as the paresis tends to diminish in amount. The patient was then referred for a complete medical and neurologic check-up, and all the findings were subsequently reported as negative. Glasses were prescribed as follows: O.D., +1.00D. sph. \ominus -0.50D. cyl. ax. 90° , with a 2^Δ base down; O.S., +1.00D. sph. \ominus -0.50D. cyl. ax. 90° , with a 2^Δ base up.

The patient reported back six months later at which time the diplopia field had not changed appreciably. The distance phoria readings in the primary position of gaze were as found at the first examination. The patient has been without symptoms and without diplopia and cannot get along without his glasses. He still can produce diplopia easily by looking to the left and up, but has developed a mannerism of keeping his head cocked in a compensatory way so that he never sees double, unless he looks for it.

QUESTIONS

House Officer: Once prisms are prescribed for a patient, does he always have to wear them?

Dr. Sloane: If the paresis clears up,

prisms will be rejected by the patient.

House Officer: Can you obtain this amount of prismatic effect by decentering the lenses?

Dr. Sloane: Displacement of 1 mm. in a 1-diopter lens will give 1/10 of a prism diopter prismatic effect, so obviously one cannot obtain sizable prismatic effects in weak lenses. In this case prisms were ground into the prescription.

House Officer: How can you tell the presence of a prism in a spectacle lens?

Dr. Sloane: There are three methods:

1. A difference in thickness of opposite edges of a lens would make you suspect a prism, but this would only hold true if the prisms were fairly strong.
2. The lensometer readings will be displaced from the center even though the lens is set in the instrument with its geometric center properly placed.
3. If you view a straight line through the geometric center and along the principal meridian of the lens, the line will not be continuous within and outside the lens, but will be displaced according to the power of the prism.

House Officer: If this man were presbyopic, how would you manage his glasses in bifocals?

Dr. Sloane: As a rule, any person who has to tip his head back over one shoulder cannot get along well with bifocals because he will look through different portions of each segment. Therefore it is advisable in such cases to avoid their use and to insist upon single vision glasses.

House Officer: Is it advisable to divide the prisms between both eyes or to incorporate them before one eye alone?

Dr. Sloane: Prisms ground into lenses make their cost greater, therefore, when it is possible we should correct the defect with prisms before one eye, but this

is only effective if the total amount of prism power is not in excess of approximately 1½ prism diopters. The advantages of dividing prisms between two eyes are: (1) Both lenses weigh approximately the same so there is no tendency for the lens to hang lower on one side. (2) The spectacles are less conspicuous. (3) There is less chromatic aberration and other distortions which occur when one looks through strong prisms.

House Officer: When do you operate for the relief of diplopia in a paresis?

Dr. Sloane: There are two criteria. (1) If the amount of prismatic correction, in order to remove symptoms, is over 8 prism diopters, correction prisms are usually not satisfactory. (2) One should wait a certain period of time to allow the muscle to recover, if it is going to, and also to allow for secondary contractures which are likely to be the case, so that one can better judge what type and how much surgery should be done.

House Officer: How long is this time?

Dr. Sloane: Most persons agree that six months is a fair waiting period.

House Officer: In this case, if surgery had to be done, which muscle and what procedure would be indicated?

Dr. Sloane: Probably a weakening operation on the yoked muscle of the opposite eye. In this case a myectomy of the right inferior oblique muscle.

House Officer: What is the rationale for selecting the right inferior oblique?

Dr. Sloane: Hering's law suggests that one must innervate yoked muscles alike. Thus, a weakened right inferior oblique would require greater innervation, as does the paretic left superior oblique, thus tending to equalize their resultant activity and lessen the diplopia. Of course one can, theoretically, also do a strengthening operation to the left superior rectus for the same reason.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

November 4, 1946

DR. BENJAMIN FRIEDMAN, *president*

CLINICAL ANATOMY OF VISUAL PATHWAYS

DR. MORRIS B. BENDER spoke on this subject during the instructional hour.

NEUROLOGIC LESIONS OF OPTIC PATHWAYS

DR. I. M. TARLOV described two cases of meningioma of the sphenoidal ridge. The first case was of a man who had been operated two years previously, and the second was of a woman who was operated four years previously. Proptosis was present in both cases and X-ray studies showed absorption of the sphenoidal ridge. Although both cases showed excellent results following operation, there was very little, if any, recession of the proptosis, which was marked in one case and slight in the other. The intraorbital, as well as the intracranial portions of the tumor, were removed in both cases.

Dr. Tarlov also presented a case of orbito-ethmoidal osteoma, which was operated. The sudden development of an intracranial, frontal pneumatocele in this patient was associated with a contralateral hemiplegia. This disappeared completely after removal of the osteoma, evacuation of the air within the frontal lobe, and repair of the dural defect in the floor of the anterior fossa with fascia lata graft. Other orbital tumors were discussed and an X-ray picture of a calcified orbital meningioma was shown. Dr. Tarlov concluded by pointing out the advantages of the trans-frontal approach for orbital tumors, many of which have intracranial extensions.

Discussion. Dr. Alfred Kestenbaum stated that there are three types of meningioma which are of importance to the ophthalmologist:

1. Meningioma of the olfactory groove. This is the most frequent but not the only cause of the Foster-Kennedy syndrome.

2. Suprasellar meningioma. Suprasellar tumors may result in bitemporal hemianopia which sometimes starts as a bitemporal hemianopia central scotoma. The nasal half of the macular area of the field is always preserved.

3. Meningioma of the sphenoid ridge. This condition may show an ophthalmic syndrome, which if fully developed consists of the following signs: (a) Symmetrical exophthalmos—exophthalmos without lateral or vertical displacement of the eye, as is often seen in orbital tumors close to the eye. (b) Negative resistance-sign—the eye can be pressed backward as normal; whereas, in tumors immediately behind the eye, a hard resistance is felt. (c) Eye-muscle palsies—may be due to either a lesion of the nerves or to a direct pressure on the muscles. (d) Retrobulbar lesion of the optic nerve caused by pressure—may produce a central scotoma and temporal pallor, and later total blindness and total “descending optic atrophy” of the disc. (e) Disturbances of the pupillary reactions—depending upon the damage to the optic nerve.

Aneurysms of the brain arteries have become of great importance to the ophthalmologist in recent years. The following types are of special interest:

1. Arteriovenous aneurysm of the carotid artery in the cavernous sinus. This causes the well-known picture of pulsating exophthalmos.

2. Simple aneurysm of the carotid artery in the cavernous sinus without arteriovenous communication. It may be the cause of eye-muscle paresis but there is neither exophthalmos nor pressure on the orbital part of the optic nerve.

3. Aneurysm of the carotid artery after it passes through the dura and arachnoid within the subarachnoid space. In this case the visual field changes may become manifest in two forms because the carotid lies laterally to the chiasm: (a) Pressure on the chiasm from the side may result in a nasal defect in the field of one eye (not a binasal defect). (b) Pressure of a big aneurysm of the right carotid artery upon the right optic nerve, as well as upon the right optic tract, may result in a combination of left-sided hemianopia and loss of the macular vision in the right eye.

4. Aneurysm of one of the anterior arteries of the circle of Willis. The anterior cerebral and anterior communicating arteries may cause pressure on the chiasm from in front and above and at the same time on one optic nerve. In this case the visual field will show bitemporal hemianopia and loss of the macular area of the eye homolateral to the aneurysm.

5. Aneurysm of the posterior part of the circle of Willis (as of a posterior communication or of a posterior cerebral artery) often affects the oculomotor nerve. In recent years it was emphasized that isolated palsy of the oculomotor without any other signs should arouse the suspicion of such an aneurysm.

FIELD CHANGES IN PITUITARY SYNDROMES

DR. DANIEL KRAVITZ stated that to the average ophthalmologist, field changes in the pituitary region means bitemporal field defects. However, in no other part of the brain are the field changes so varied and so difficult to interpret. It is only in this region that one can get blindness in one eye or both, binasal or bitemporal defects,

homonymous hemianopias, central scotomas, and all manners of combinations of these. For a proper understanding and interpretation of these variations, Dr. Kravitz stressed the need for a knowledge of the anatomy, embryology, and physiology of this region.

Dr. Kravitz concluded that to wait for the typical field changes before making a diagnosis would frequently end in tragedy. Therefore, some knowledge of the anatomy and physiology of those parts of the brain which may affect visual pathways is essential.

Discussion. Dr. Thomas H. Johnson opened the discussion by saying that the variation in the visual fields is due to the relation of the chiasm to the surrounding structure. Walker and Cushing found in a series of 183 cases of pituitary tumor that 148 cases showed field disturbance. Bitemporal hemianopia was present in 47 cases, homonymous in 22 cases; 79 patients were blind in one eye, and the type of hemianopia could not be determined. De Schweinitz found homonymous field defects in 6 percent of his cases, and Hirsch in 7 percent. The tumors may not grow symmetrically, but may encroach more upon the structures of one side than the other. In a study by Schaeffer, it was found that the chiasm may lie in front of, directly over, or behind the pituitary.

In about three fourths of the specimens, the anterior and often the greater part of the chiasm rests on the sella diaphragm. At times there may be a vertical space of 10 mm. between the pituitary and the chiasm. It is obvious that neoplasms, having their origin in tissues beneath the chiasm, give early defects in the upper temporal quadrants; while those arising from tissues above the chiasm show defects in the lower temporal quadrants.

Before any of the changes produced by pressure manifest themselves, however, scotomas may be present. The most com-

mon location of the scotomas is in the cecocentral area, not uncommonly in the lower temporal quadrants but rarely in the nasal half of the field. They are prone to be bilateral. These scotomas progressively widen into quadrant defects and hemianopias.

De Schweinitz supports the theory of Fuchs, that they are caused by toxins, thrown off from the neoplastic tissues into the cerebrospinal fluid in the cisterna chiasmatica, which bring about a retrobulbar neuritis.

Walker and Cushing think scotomas of this character can not be explained on a mechanical basis alone, and that an explanation based on hypersensitiveness of the papulomacular bundle, or toxic actions, is unsatisfactory but must be accepted in the light of our present knowledge. They believe that pressure upon the chiasm from the tumor alone does not account for all of the field changes, but that traction and tension upon the crossed fibers, and counterpressure from the anterior clinoid processes, dural bands, and the bony walls of the optic foramen, are important factors, as well as pressure on the tracts farther back against the peduncles. They report, on the other hand, a case in which pressure by the neoplasm had greatly displaced one of the optic tracts, without producing any change in the visual fields or optic discs.

Fay and Grant reported a case of pituitary tumor which pressed the chiasm against the anterior cerebral artery, causing the artery to indent the optic tract and thus produce an homonymous hemianopia.

Traquair's hypothesis is that field defects in chiasmal lesions are due to pressure, traction, and the action of toxins; that the pressure does not produce the changes by direct action upon the chiasm but by impeding venous return and producing arterial ischemia. He thinks the

scotomas indicate activity of tumor growth.

It is a common belief that the maculopapular bundle is very susceptible to the effects of toxins, and the toxin theory regarding production of scotomas is probably acceptable to most ophthalmologists. A bilateral scotoma in the visual fields, a scotoma in one field and slight upper or lower temporal defect in the other, or a slight bilateral upper or lower temporal defect should put one on guard against a lesion of the chiasm.

As the optic atrophy is a descending one, the disc may not become pale until the hemianopia has been in existence for some time. As a rule the nerve head is a pink, waxy color. The disc outline is more often than not blurred by a deposit of connective tissue; as is the lamina cribosa.

Internal hydrocephalus may distend the third ventricle to such a degree as to press upon the chiasm, erode the bony structure around the sella, and bring about a hemianopia. Dr. Johnson said that he had had such a case in a 9-year-old boy. These cases, he said, showed a papilledema rather than a pale optic-nerve head. He also spoke of a case in which an aneurism of the circle of Willis simulated a pituitary neoplasm. All verified recorded cases of such aneurisms have had a paralysis of the third nerve.

Gliomas of the chiasm produce very irregular and early field defects, may show an enlargement of the optic foramen, and may be accompanied by a more or less general neurofibromatosis. Dr. Johnson concluded his discussion by remarking that, since most lesions which produce the chiasmal syndromes erode the clinoid processes or widen and distort the cells, careful X-ray studies by a skilled roentgenologist will clarify the diagnosis.

Dr. Bender said that in the neurologic clinics of Bellevue and Mount Sinai Hospitals, they are not able to make exact

localization as to whether the lesion is above or below. In some cases, autopsy reveals tremendous tumors near the chiasm with no visual-field defects; in others, there is tumor depression of the entire chiasm. Dr. Bender said that it was not possible to determine whether the tumor was anterior, posterior, or lateral.

Dr. Alfred Kestenbaum said that the two terms—bitemporal hemianopic central scotoma and true central scotoma—must be sharply separated from each other.

Because the fibers originating from the nasal halves of the two maculas cross the midline in the most posterior part of the chiasm, involvement of the chiasm from behind, that is by a suprasellar tumor, may cause a bitemporal hemianopic central scotoma. In each field the nasal half of the macular area is damaged; whereas, the temporal half is preserved. In other words, there is "macular splitting." Visual acuity may still be 20/20. Completely different from this picture is the real central scotoma, as it is seen in cases of pressure on, or in disease of, the optic nerve. Here the temporal as well as the nasal half of the macular area is involved. The vision may be diminished down to eccentric vision of fingercounting at two meters. When the focus involves the chiasm from above, the field defects start in the inferior quadrants. When the focus involves the chiasm from below, the field defects start in the superior quadrants. If the focus involves the chiasm from in front, an optic nerve must be involved also, resulting in a central scotoma of that eye. If the focus involves the chiasm from behind, there cannot be a real central scotoma, for the nasal halves of both macular areas must be preserved.

The combination of these rules permits a certain degree of accuracy in the localizing of these lesions. Dr. Kestenbaum concluded by remarking that the

final diagnosis has to be made by the neurologist in conjunction with all other neurologic symptoms.

Dr. Kravitz (in closing) remarked that he agreed with Dr. Kestenbaum that experience in taking visual fields in brain tumors is very important. He said that tumors pressing on the chiasm far in front or in the back will show that anatomists are correct. The anatomic arrangement is important. All optic chiasms are not the same, nor are all optic nerves. Some are fixed by dura; some are short and some are long. If the chiasm is fixed, then early symptoms appear; if mobile, they take a great deal before showing defects. In general, there is confusion due to various anatomical changes and variations within the skull.

Bernard Kronenberg,
Secretary.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

October 24, 1946

DR. BURTON CHANCE, *chairman*

ADENOCARCINOMA OF LACRIMAL GLAND.

DR. I. EDWARD RUBIN (by invitation) presented a case of mixed tumor of the lacrimal gland, which is rare, there being less than 300 cases reported in the literature. Although it is the commonest disease of the lacrimal gland, the origin of this tumor is still a controversial subject. Grossly and histologically it resembles a mixed tumor of the salivary gland.

The signs and symptoms of mixed tumor of the lacrimal gland are those of a slowly progressive, unilateral, orbital tumor. These include proptosis with displacement of the globe downward and slightly nasalward. A mass felt in the

region of the lacrimal gland is a constant, diagnostic sign. There is also limitation of motion, diplopia, impairment of vision, fundus changes, usually no pain, lacrimation, and exposure keratitis.

Recurrence of this tumor frequently occurs. It is often incompletely removed, and has a strong tendency toward bony invasion. It may become malignant after many years.

X-ray therapy has little noticeable effect. Surgical removal is the best treatment, and should be as radical as possible. If bone is involved, it should be resected. If the orbital tissues are involved, an immediate exenteration is indicated. Four surgical approaches were discussed: the direct, the transconjunctival, the Kronlein, and the frontal flap with removal of the roof of the orbit.

A case of mixed tumor of the lacrimal gland in a white man, aged 35 years, was presented. The case had been followed from childhood. When the patient was 10 years of age, proptosis was first noted. At the age of 16 years, a mixed tumor of the left lacrimal gland was supposedly completely excised. After 11 years, the tumor first recurred. It was again excised five years later when the patient was 33 years of age. Microscopically, the tumor was reported as a mixed tumor. Within 21 months it recurred, and this time it involved the optic nerve producing papilledema. Intracranial extension was suspected, so a frontal craniotomy with removal of the roof of the orbit was performed. This was followed by a complete exenteration of the orbit. A large tumor, apparently arising from the region of the lacrimal gland, extended posteriorly to compress the optic nerve. Pathologically, the tumor tissue was adenocarcinomatous.

In conclusion, Dr. Rubin thanked Dr. Spaeth for the privilege of presenting this very interesting and unusual case. He also acknowledged to Dr. Zentmayer that this

was a follow-up on the case he had reported 18 years ago, and thanked him for his coöperation.

Discussion. Dr. Jacob H. Vastine, 2nd, said that Dr. Rubin had made such a complete presentation of this subject that little remained to be discussed.

Surgery is probably the treatment of choice in cases of mixed tumors, whether of the salivary glands, nasal accessory sinuses, or lacrimal glands. In some cases, surgery is impossible or refused, and in these cases irradiation has value. This may be administered either as X-ray therapy, radium therapy, or both. The irradiation may be expected to effect regression of malignant tissue, and to retard the growth of the benign elements. There is sufficient proof of the value of irradiation to recommend it as a postoperative measure.

It is interesting to note that this patient was first operated upon in 1927. He received immediate postoperative X-ray therapy, administered by Dr. Henry Pancoast, and did not have a recurrence for 11 years. He was treated by me in 1939 and 1940, and the tumor remained quite stationary until 1944. He was again operated upon in 1944, and at that time received no postoperative roentgen therapy. It is quite striking that there was a rapid recurrence, and within two years another tumor was removed from the same site. This time it was malignant. The question may be asked whether postoperative treatment in 1944 would have delayed recurrence or malignant change. X-ray studies, made by me in 1939 and again in 1946, showed a pressure erosion of the roof of the orbit in the region of the lacrimal fossa. This defect remained unchanged.

Roentgenograms and photographs were presented of an unconfirmed case treated by Dr. Pfahler and me, in 1930. There was marked ptosis and proptosis which regressed following roentgen therapy

alone. The patient had been studied by Dr. Goalwine in New York, in 1930, at which time a defect in the lacrimal fossa of the orbit was found. This was similar to that in the case presented by Dr. Rubin. That patient was referred to Dr. Pfahler for roentgen therapy in 1930. A presumptive diagnosis of a mixed tumor of the lacrimal gland was made. Roentgen therapy alone was administered by Dr. Pfahler and by me. The patient was entirely well when last seen five years later.

Dr. Robert A. Groff congratulated Dr. Rubin on his excellent presentation and said that it was not only interestingly told, but also covered the subject thoroughly.

Prior to operation of the patient who constitutes the case report in the author's paper, it was thought that the orbital tumor had entered the orbit through the bony defect in the orbital roof, as seen in the X-ray pictures, or that it had extended along the optic nerve into the cranial cavity. When the anterior fossa was explored, there was no evidence of tumor. Upon removing the roof of the orbit, it was quite obvious that the tumor had extended throughout the tissue in the orbit, and it was difficult to identify normal structures. For this reason, he had contented himself with excising part of the tumor with the idea that Dr. Spaeth, at a later date, should remove the entire contents of the orbit.

The procedure of frontal craniotomy and removing the roof of the orbit is very simple and safe. It is done entirely extracranially so that the subdural and subarachnoid spaces are not entered nor contaminated. The exposure it affords of the structures in the orbit is excellent. It is recommended not only as an easier method to remove orbital tumors completely, but also as the procedure for decompression in exophthalmos. The procedure should be done jointly by the neurosurgeon and the ophthalmologist.

Dr. Edmund B. Spaeth (in closing)

said that as soon as the report of the biopsy from Dr. Groff's transfrontal operation had been received, a radical exenteration of the orbit had been done. The reason for the massive and immediate postoperative radium therapy was not because there originally had been a mixed-cell tumor, but because a clean, clear-cut, rapidly developing adenocarcinoma was reported.

One other case of mixed-cell tumor of the lacrimal gland is under observation, and we are wondering with this occurrence what is going to happen to that case. The case was operated, using the Kronlein technique, and received X-ray therapy in massive doses postoperatively. The report we received at the time of the surgery, after examination of a frozen section, was mixed-cell sarcoma. That is why we proceeded with massive X-ray therapy. Forty-eight hours later, a second report changed the diagnosis to mixed cell tumor. I am rather curious to know what is going to happen to this young lady. She has a practically complete ptosis following surgery, and declines surgery for this ptosis. I am not urging her. I would much prefer to let that alone for the time being. She is developing a sequestrum in the lateral wall of the orbit, and I would not be at all surprised if it becomes necessary to perform a sequestrectomy of that area of the zygoma.

PERIARTERITIS NODOSA

FRED HARBERT, CAPT. (MC), U.S.N. AND SAMUEL D. MCPHERSON, JR., LIEUT. (JG), (MC), U.S.N.R. (by invitation) presented a case of scleral necrosis in periarteritis nodosa which was published in the June, 1947, issue of the *JOURNAL* on page 727.

HYDRATION AND TRANSPARENCY OF CORNEA

WILLIAM M. HART, PH.D. (by invitation) said that recent work (Cogan and Kinsey, *Science*, 1942, volume 95, pages

607-608) has emphasized the degree of hydration as the chief determining factor in transparency of the cornea and as responsible for the optical difference between cornea and sclera. According to this concept, the cornea is endowed with a dehydrating mechanism to keep down its water content. When this mechanism fails, swelling occurs and, therefore, opacification. The sclera, on the other hand, is always opaque, because of the absence of any such mechanism. If, however, the sclera is deliberately dehydrated, as by drying in air or placing in glycerine, it also becomes "transparent."

In the present study, swelling and transparency of beef corneas were noted in various buffer solutions, all of which were adjusted to the same osmotic activity (8.94 atmospheres) by adding glucose. Throughout this study an absolute disparity was found between the degree of hydration and the turbidity of the cornea.

The cornea may be characterized as a lyophilic colloid system inasmuch as it shows behavior analogous to gelatin and fibrin under like conditions. Like many specimens of gelatin, it has an isoelectric point of pH 4.6 as shown by the swelling minimum.

Various factors were found to affect the transparency of the cornea independently of the water content. It is suggested that these factors operate by affecting the refractive index of the water or of the micelles, or both.

Affecting the micellar refractive index are: (1) temperature, (2) electrolytes, (3) isoelectric point, (4) dissociation, (5) association, (6) mechanical stresses (as in birefringence), (7) pH, (8) hysteresis, and (9) coacervate formation (due to protein-lipid-carbohydrate complexes).

Affecting the refractive index of the water are: (1) pH, (2) electrolytes, (3) nonelectrolytes, (4) surface tension, and (5) temperature.

According to this theory, when the re-

fractive index of the solvent water in the cornea becomes markedly different from that of the particles, turbidity results.

The practical potentialities of these observations were shown in the fact that it was possible to clear the corneal opacities which occur spontaneously in cattle. Further work will be directed toward such an attempt in the intact animal.

Discussion. Dr. Francis Heed Adler said that it would be very difficult for anyone to discuss this paper after hearing it for the first time, and it was quite impossible for him to do so, but he could not refrain from mentioning how delighted he was that work of this type was being done in Philadelphia. The results of investigations of this character do not remain long in the laboratory. They have definite practical significance.

A few years ago, Cogan in Boston, and others, began experiments on the permeability of the cornea and its property of imbibition, which are being applied in the clinic. They showed the the normal cornea soon becomes less transparent if bathed with a solution of ordinary normal salt or with hypotonic solution. In order to keep the cornea clear during an operative procedure, such as detachment of the retina, most surgeons now keep the cornea flushed with a salt solution of 1.5-percent strength. They also showed that most of the deleterious effect of cocaine solutions was due to the fact that they are hypotonic. The question of turbidity of the cornea with loss of its transparency becomes increasingly important with the operation of transplantation of the cornea.

For the last few years, Dr. Leopold has been interested in transplanting corneas from frozen dried material. Although these transplants take well, they soon become opaque and remain so. The answer to this problem is to be found in the kind of work which Dr. Hart is doing, and I trust that he will be encouraged to continue it.

Dr. William M. Hart (in closing) thanked Dr. Adler for his comment and said that, as shown in the data, the dehydrated cornea, when rehydrated, is often optically better than normal cornea. He and his co-workers were not aware of Dr. Leopold's work, of course, which was carried on under conditions of war secrecy, but the next point they had in mind was to try to transplant corneas from the dried state.

Opacity of the cornea is a very common condition in cattle. A number of such eyes were brought to the laboratory. Some of them had deep ulcer craters, which he presumed to be scar tissue. Such corneas can be cleared in one of two ways. They can be dried in air, in which case they become clear as normal corneas; or, they can be allowed to swell in appropriate strength hydrochloric acid or various buffer solutions. Those corneas which have been dried may be rehydrated and then do not again become opaque.

George F. J. Kelly,
Clerk.

CHICAGO
OPHTHALMOLOGICAL
SOCIETY

DR. WILLIAM A. MANN, *president*

October 17, 1946

CLINICAL PROGRAM

The clinical meeting was presented by the Department of Ophthalmology, University of Chicago.

BOECK'S SARCOID DISEASE

DR. BYRON L. GIFFORD presented two cases of this disease.

Case 1. Mrs. D. R., aged 36 years, was first seen in July, 1946, with a history of pain and redness in the right eye in September, 1945, followed by remission, and

exacerbation of redness in April, 1946, with concurrent redness of the left eye. At another clinic, a biopsy of a cervical lymph node had been made, chest films had been taken, and a diagnosis of sarcoid disease was made.

Aided vision was: R.E., 20/70; L.E., 20/30. Both eyes showed seroplastic uveitis without nodules. There was a heavy increase in aqueous flare with low cell count (2 to 3 per smallest slitlamp field), very large mutton-fat keratic precipitates deposited on the corneal endothelium, many heavy posterior synechiae, and an uveal pigment and cyclitic membrane on the lens capsule. The right eye showed more involvement than the left. The right fundus showed a red reflex only; in the left fundus, detail was blurred, but no pathologic condition was noted.

In August there was increased reaction in both eyes; vision decreased to: R.E., 20/300; L.E., 20/100. Two months later both eyes showed rather remarkable beginning spontaneous remission, especially the left eye in which aqueous-flare increase was minimal, with only an occasional floater, and marked decrease in the number of keratic precipitates. At this time vision was: R.E., remained 20/100; L.E., returned to 20/30+.

Only a single lymph nodule was found in the axilla. X-ray pictures of the chest showed large round hilar masses bilaterally with absence of parenchymatous lesions; no sarcoid rarefactions were noted in X-ray studies of hands and feet. Tuberculin sensitization, skin tests for lymphogranuloma, serology tests all gave negative findings.

Case 2. Mrs. J. J., aged 25 years, first noted a growth in her left eye in December, 1945. Prior to that time she had had a "nervous breakdown," with general weakness, marked tremor, and weight loss, without cough or elevation of temperature. A chest film taken in 1944 was

reported as negative. Her mother supposedly died from tuberculous infection.

When seen in March, 1946, the corrected vision was: R.E., 20/16; L.E., 20/100. The left eye showed a large, yellowish-pink, slightly lobulated tumor mass filling about one third of the anterior chamber from the inferior nasal limbus to the pupil and pressing against the cornea. This was seen to be attached to the iris and was covered with a fine network of vessels, all originating from the iris. The aqueous flare was increased. There were occasional floaters and many large mutton-fat keratic precipitates on the corneal endothelium. The 2-mm. pupil was fixed to the lens, which showed a complicated cortical cataract. No fundus details were seen.

In the right eye, the cornea was clear, with no increase in aqueous flare, no floaters, and no keratic precipitates. The iris showed two tiny bulges, about 1 mm. in size, near the limbus and at the pupillary margin. The pigment border of the pupil was slightly irregular with no frank pigment exfoliation.

During subsequent weeks, a sarcoid uveitis in the right eye was observed under the slitlamp, from the early incipient stage to a full-blown nodular and seroplastic type. The pupil border became stringy, the iris stroma appeared swollen, aqueous flare gradually increased, a few floaters appeared, and within five weeks, the tiny bulges of the iris pigment layer became typical Koeppe nodules. Abundant mutton-fat keratic precipitates were deposited on the corneal endothelium. More Koeppe nodules formed at the pupillary border, from which site posterior synechiae developed.

The skin of the flexor surface of both forearms showed many small subcutaneous nodules. X-ray pictures of the chest showed extensive infiltration at each hilus, along the mediastinum and in both upper

lobes, compatible with sarcoidosis. X-ray films of feet and hands showed no rarefaction. Routine serology and other laboratory and skin tests gave negative reactions. Biopsy of one of the subcutaneous nodules of the arm showed, on microscopic section, a mass of highly vascularized granulation tissue in which epithelioid cells were occasionally arranged to form tuberculoid structures with Langhans's type giant cells; no caseation necrosis was seen.

X-ray therapy to the tumor mass of the left eye was given at weekly intervals. At the end of the fourth week, the tumor mass appeared to shrink in size about 20 percent, but regained its original size during the remainder of 10 treatments.

When the patient was last seen in August, 1946, the vision of the right eye remained 20/13, but vision of the left eye was reduced to hand movements at two feet. Tension remained within normal limits during the time of observation.

TOXOPLASMOSIS

DR. BYRON L. GIFFORD said that A. P., a man, aged 38 years, was seen in September, 1946, with a history of poor vision in both eyes since childhood. The left eye had always been the better until five years ago, when vision gradually decreased until there was no light perception in this eye. Vision was: R.E., 9/200.

The right eye showed myopia of 3 diopters, a large macular chorioretinal coloboma, degenerative papulomacular bundle, temporal optic atrophy, anomalous retinal correspondence, at least 10 degrees nasalward and 10 degrees below the posterior pole. The left eye showed a microcornea (R.E., 11.5 mm., L.E., 9.5 mm.), iris rubeosis, blockage of angle of anterior chamber by the adherent iris root, and a bizarre complicated cataract with white, sculptured, statuelike opacity. The fundus showed an enormous posterior staphy-

loma. The eye was glaucomatous (Schiotz, R.E., 22 mm. Hg; L.E., 54 mm.). All laboratory tests were negative.

In spite of the lack of history of the sequence of events, the findings would indicate an early, possible fetal infection, leading to the numerous present complications. Tests will be made to confirm the diagnosis of plasmosis.

BILATERAL RETROLENTAL FIBROPLASIA

DR. BARBARA SPIRO presented a case of retrolental fibroplasia with fetal iritis and secondary glaucoma.

Case report. D. M., a white baby girl, aged 1½ years, was first seen in February, 1946. The baby and her twin brother were born after a 6½ months uneventful pregnancy; the boy died shortly after birth. The mother noted the girl's poor vision at the age of 3 or 4 months.

There was questionable light perception in each eye, the left apparently the better one. Bilateral enophthalmos and epicanthus were noted. The eyes exhibited bilateral searching nystagmus. The right cornea measured 8.5 mm., with central opacities; the left, 9 mm. Both anterior chambers were very shallow. Both irides were of fetal-blue color, atrophic and with vessel formation. Whitish nodules were noticed at the iris frill. The iris was bound down by extensive synechiae with a 2-mm. pupil; the left pupil could be dilated to 5 mm. The lenses were fairly clear and behind each one could be seen a whitish-gray mass with small blood vessels on the surface. On the left side, a few fundus vessels and a grayish-red reflex could be made out; on the right, nothing beyond the gray mass. Ocular tension with Schiotz and Souter tenometer was about 30 mm. Hg on the right and 15 mm. on the left.

Pediatric examination showed the baby to be normal otherwise, although some mental retardation was noted.

BILATERAL RUBEOSIS IRIDES

DR. BARBARA SPIRO said that D. P., a 49-year-old white man, was shown before this society in May, 1945. At that time he stated that his vision had started to diminish two years before. He had diabetes mellitus which was controlled with diet and insulin. Vision was: R.E., 20/100; L.E., 8/200. The striking findings were bilateral iris atrophy with rubeosis irides of the left eye, advanced diabetic retinopathy of both eyes, and rete mirabile of the right eye. Since that time the patient has been under good medical care. Vision has continued to decrease to hand movements at two feet in the right eye, and light perception in the left. He now has bilateral rubeosis irides, the retinopathies have become more marked, and he has bilateral rete mirabile.

BILATERAL RETROLENTAL FIBROPLASIA

DR. BARBARA SPIRO presented R. S., a 6-months-old white boy, first seen in September, 1946. He was born 2½ months prematurely after an uneventful pregnancy. The poor vision was noted at the age of 2½ months.

Examination revealed bilateral sunken eyes and bilateral nystagmoid ocular movements. The corneas were clear and measured 9 mm., horizontally. Both anterior chambers were extremely shallow. The irides were fetal blue in color, the pupils could be dilated to 3.5 mm., and the irides were bound down with numerous posterior synechiae. Some anterior synechiae were seen peripherally. The lenses were clear. Behind them were large whitish-gray masses, extending into and including the retinas. A red fundus reflex could be obtained in the periphery.

No other abnormal physical findings were noted. The psychologist reported a dull rating, but was optimistic concerning the child's development compared to that of similar premature blind babies.

RETINITIS PIGMENTOSA SINE PIGMENTO

DR. S. J. ALEXANDER said that this 31-year-old white man complained of poor night vision of 15 years' duration. Vision was: R.E., 20/16-2; L.E., 20/13-2. Examination revealed normal external eyes and normal anterior segments.

The fundi showed essentially normal discs, reduction in size of the vessels, and a very few small pigment clumps in the periphery. The retina had a slightly pale-gray, granular appearance. Visual fields revealed bilateral ring scotomas.

On questioning, the patient said he knew of no other similar eye difficulty in the family. However, his mother was examined a few days later and identical eye findings were seen.

OPTIC ATROPHY, RETROBULBAR NEURITIS, AND BRUCELLOSIS

DR. S. J. ALEXANDER presented C. S., a 22-year-old ex-marine, who complained of sudden loss of vision in the right eye one month previously. Several days later vision had returned to light perception, which did not improve. A tentative diagnosis of brucellosis was made because of a rather constant, low-grade fever, enlarged lymph nodes and spleen, and previous questionable blood cultures for *Brucella*.

Vision was: R.E., light perception and projection temporally only; L.E., 20/20+2. A right divergent strabismus was found. The adnexa and anterior segment were normal. The right pupil reacted weakly to light but well consensually; the left reacted well to light but poorly consensually, normally for accommodation. Examination of the fundi showed the right disc to be white and slightly elevated with blurred margins. The left disc was normal. The veins showed marked congestion, tortuosity, and segmentation. Arteries were tortuous and somewhat reduced in size. A few minute

striate hemorrhages were noted. The right foveolar reflex was absent. The left macula was normal. There was slight edema of both retinas.

To confirm the diagnosis of brucellosis, a lymph-node biopsy was taken. The section showed lymphoid lipoidosis of the Hand-Schüller-Christian type. The ophthalmologist, however, could only say that this was an aberrant form of optic atrophy.

OPTIC ATROPHY WITH ARACHNOIDITIS

DR. A. W. FELDMAN presented J. F. K., a white woman, aged 45 years, with a history of hypertension of 10 years' duration and various complications for which she had been under medical and surgical treatment since that time. An examination in April, 1946, disclosed papilledema with pallor of both discs and sluggish pupillary reflexes. In December, 1945, she had fallen, sustaining a Colles' fracture and a contusion over the right eye.

Ophthalmic examination in August, 1946, showed no light perception in either eye. Blood pressure was 242/130 mm. Hg. The pupils measured 5 mm. and were fixed. An irregular searching nystagmus was present. The discs were pale gray and showed 2 diopters of papilledema. There was peripapillary and perimacular edema bilaterally, but the maculas were not remarkable. The vessels showed irregularity of lumen size. The arteries were markedly sclerotic, some being of silver-wire variety, and the A.V. ratio was about 1:3. There were no hemorrhages or exudates.

Lumbar puncture revealed spinal-fluid pressure of 350 mm. which rose to 550 mm. with jugular pressure. The fluid was clear, and the Pandy test was negative. X-ray films revealed normal optic foramina. Subsequent ventriculography showed the ventricular system to be in

the midline and moderately dilated, with no apparent cause for dilation. Because of the history of injury, findings of bilateral optic atrophy, and increased intracranial pressure, with absence of X-ray or clinical evidence of intracranial neoplasm, a diagnosis of chronic arachnoiditis was made. A subtemporal decompression was performed in September, 1946, at which time it was noted that the arachnoid was grayish and thickened along the vessels of the cortex; elsewhere, it appeared essentially normal. Postoperative lumbar punctures were done daily and then every two days. She was free from headache when discharged to be followed in the neurosurgical outpatient department.

FAMILIAL RETINAL HYPOPLASIA WITH NYSTAGMUS

DR. A. W. FELDMAN presented four patients with familial retinal hypoplasia with nystagmus because of the findings in a father and three children.

Case 1. R. T., a white man, aged 38 years, gave a history of poor vision for as long as he could remember. He had first worn glasses at the age of 10 years. His father and three siblings were myopic. There was no family history of night blindness. Vision was: R.E., 20/70; L.E., 20/100. The right vision could be corrected to 20/30; the left was unchanged. Examination revealed a right divergent squint of 10 degrees, a coarse horizontal nystagmus, and normal anterior segments. The fundi showed bilateral thinning of the retinas and normal discs, vessels, and maculas. Bjerrum fields were within normal limits.

Case 2. The son, aged eight years, had worn glasses since the age of four years. Vision was: R.E., 20/50-2; L.E., 20/70+1; corrected to 20/50-2 in each eye. There was an alternating convergence of 10 degrees with preference for right-eye fixation and a coarse nystagmus. The fundi showed the retinal thin-

ning noted in the father's eyes.

Case 3. A five-year-old daughter had never worn glasses but her parents had noted poor vision and nystagmus. Vision was: R.E., 20/100; L.E., 20/70-1. There was an alternating convergence of 15 degrees with preference for left eye fixation, coarse nystagmus, and retinal thinning bilaterally.

Case 4. Another daughter seen one year later at the age of eight years had worn glasses for three years. Vision was 20/40-2 in each eye, improved with correction to 20/40+3 in the right eye, and 20/50-2 in the left eye. There was an alternating convergence of 15 degrees with preference for left-eye fixation. The same type of nystagmus and bilateral retinal thinning was noted.

VON RECKLINGHAUSEN'S DISEASE

DR. PAUL G. WOLFF presented H. F., a 30-year-old white man, who was seen in consultation with the Surgery Clinic following plastic repair of the left temporal area. He was born with a mass of neurofibromatosis of the left side of the head.

Examination showed an extensive soft-tissue lesion of the left side of the head from the orbit to the occiput, with underlying bony changes, left optic atrophy, right and left gray choroidal lesions interpreted as fibromata, numerous small nodules of right and left irides, increased visibility of the corneal nerves, café-au-lait spots, and small soft painless nodules of the skin. The movement of the proptosed and grossly displaced left globe was disturbed and caused occasional diplopia in spite of the low (6/200) acuity. The patient's I.Q. was seemingly normal. No information of value as to heredity factors was available.

GROENBLAD-STRANDBERG SYNDROME

DR. C. KEITH BARNES said that J. B., a 46-year-old white man, gave a history

of intraocular hemorrhages for 23 years. The patient stated that he bruised easily and that his dentist had always been uneasy about his bleeding.

Examination disclosed a classical picture of Groenblad-Strandberg syndrome. There were extensive angioid streaks of both fundi; extensive central chorioretinal scarring with macular involvement from resorbed choroidal hemorrhages, extensive pseudoxanthoma elasticum of the neck, axillae, cubital fossae, abdomen, inguinal areas, and rhomboidal fossae. The corneal microscope showed irregularities and sacculations of the subconjunctival arteries. Skin biopsy showed degeneration of the elastic tissue. The laboratory studies were negative except for a bleeding time of 4.5 minutes and a strongly positive intradermal test with brucellergin.

RIGHT AND LEFT TETANY CATARACTS

DR. C. KEITH BARNES said that the above diagnosis was made eight years ago when H. W., a 32-year-old man, was first seen. He gave a history of convulsions in infancy, but did not have any details. No definite evidence of parathyroid deficiency was established. The basal-metabolism rate was rather low. Blood chemistry was within normal limits.

On examination, symmetrical opacities of the lens of the right and left eyes were seen. These were of classical appearance. They were uniform, translucent, ghostlike shells of punctate opacities, surrounded by clear cortex and completely surrounding clear nuclei.

RETINAL ATROPHY WITH MACULAR DEGENERATION

DR. F. S. RYERSON said that B. W., a man, aged 36 years, complained of loss of central vision. Over a period of 12

months, beginning in 1944, his ability to read, recognize people, and judge targets steadily decreased. He was discharged from the Army with the diagnosis of bilateral macular degeneration. He could read newspaper headlines and could recognize people only within a short distance. He had noticed only slight loss of color perception. Examination at the age of 27 years was said to have shown good vision. He said the fundusoscopic examination was negative.

The patient had 15 brothers and sisters. Of these, two brothers and one sister had developed the same symptoms. One other brother and two other sisters had ocular deficiencies of undetermined nature. The other siblings and the parents apparently had no ocular defects. Three cousins had serious ocular defects.

The patient had visual acuity of 20/200 in each eye. The Bjerrum fields were essentially normal with the exception of bilateral central scotomas. Fundusoscopic examination revealed normal optic discs and normal vasculature. The macular areas showed fine granular pigmentation and loss of the foveolar reflex. They had a punched-out appearance. A few small glistening hyaline particles were seen. Peripherally, a few small pigment clumps were noted. Hearing tests, medical and neurologic examinations were negative. Serology reports were consistently negative.

SCIENTIFIC PROGRAM

- Keratoplasty (movie demonstration)—
Dr. R. T. Paton (by invitation) New York, New York.
- A New Classification of Strabismus—
Dr. S. V. Abraham (by invitation) Los Angeles, California.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, F. C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois*; Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

OPTICAL REBATES

At the June meeting of the American Medical Association, ophthalmologists and the Section on Ophthalmology came in for severe criticism and condemnation from the House of Delegates for accepting and permitting acceptance of optical rebates. This unethical practice has officially been censured by means of a resolution of many years' standing in the Section. There is no question that a very large number of members of the Section have given this resolution lip service only.

The subject has been discussed formally at many meetings of the Section.

Members will recall the effort some years ago to make the practice more acceptable by notices displayed in some physicians' and in certain opticians' offices to the effect that the optician was acting as the physician's agent only. By this subterfuge, which one can be sure was not thoroughly understood by the patient, the optician dispenses the glasses and turns back to the physician a certain percentage of the profit.

That the government does not consider this to be a sound and honest business practice is shown by the civil suits initiated a short time ago in various parts of the country, on the part of the Attorney General against certain optical houses and certain physicians. These cases have not as yet been tried and, therefore, no comment at this time is warranted, except to say that the choice of the ophthalmologists who must defend themselves appears to be pretty haphazard and unfair, like picking names out of a hat. The government's answer to this complaint appears to be that there are so many ophthalmologists involved it would be impracticable to bring them all into court.

The acceptance of optical rebates is a vestigial practice left over from the days when physicians accepted kickbacks from druggists and undertakers and split fees with other physicians and professional men. Medicine has pretty well cleaned its house of the latter practices, although fee splitting and other kickbacks undoubtedly take place here and now. The splitting of fees among physicians is certainly an infrequent event now days. On the other hand, the acceptance of rebates by ophthalmologists is unfortunately nearly universal, judging from reports from various sources.

Why should this be? The argument most frequently heard is that the patient is unwilling to pay the full fee to which the ophthalmologist is entitled because of his long years of training in a special, skilled field of medicine. Therefore, part of this fee must come from the sale of glasses. Most ophthalmologists are unwilling to place optical shops in their offices, or to do the fitting themselves, or to hire an optician to do it for them. Many, however, particularly those in the smaller communities, do just this. There is nothing unethical about it, although it

is a little repugnant to a professional man to conduct an optical business on the side. But the conscientious ophthalmologist, placed in this position, will do the optical work or see that it is done under his direct supervision and business responsibility, in order to render the best service possible to his patients.

What wrong then is done if an optical house acts for the ophthalmologist as his agent? Simply this. The ophthalmologist has no responsibility, financial or otherwise, in the running of the optical house. Theoretically, he can determine the price of the finished product under this arrangement. Practically, however, the cost of the frames and lenses is pretty well established for him, and it is at this point that the government becomes interested. The ophthalmologist, therefore, is given the difference between the wholesale cost of the glasses plus a profit to the optician and what the patient pays. The physician neither sells goods nor renders fitting service. The patient rarely understands the mechanism and the cost of the spectacles is maintained at a high level.

Many optical houses don't even bother to display a sign mentioning the agent status. Cynically, these places will notify the ophthalmologist from time to time that a certain sum is credited to him, and at the end of the month a check is sent him, with or without an invoice. One can be very sure that the patient knows nothing whatever about this deal.

Rebates form a substantial part of the ophthalmologist's income and once he becomes seduced by this pernicious and unethical practice, he is pretty well lost. If his conscience pricks him, he stills it by saying that the rebate is part of his fee. The young man, just starting into practice in a community, soon finds himself, frequently against his will, compelled to accept rebates. Pressure is placed on him by other ophthalmologists and by the opti-

cal houses themselves. If he remains firm in his conviction, he is forced into dispensing his own glasses received from a reluctant wholesaler.

In a number of instances, the ophthalmologist will accept the rebates and turn them over to a clinic or hospital or, perhaps, to some charity, thus salving his conscience, but also, at the same time, keeping alive this vicious and seductive practice.

The optical houses are eager to keep this system alive because, although it is a bookkeeping nuisance to them, the optometrist and the department store dispensers of lenses, which far outnumber the ophthalmologist, can charge the full rate for the glasses and pocket the difference between cost and selling price as their profit on the examination and dispensing. It will be illuminating and instructive to follow the government suits to see how this matter of price fixing is developed. It is obvious that the patient of the ophthalmologist who does not accept rebates, and there are a number of them, and the patient of the one who does pay the same price. The former is thus penalized financially, and it may well be that the reputable ophthalmologist is shunned because his fee is too high.

What can be done about it? The optical houses can be forced by the government to turn back the rebate to the patient himself. This is possible, but not likely at the moment, for the opposition by the optometrists and department stores is a powerful one. The only other escape is for each ophthalmologist to refuse to take rebates in any form whatever, charge and collect his own fee based on the value of his services to the patient, and to inform the latter so that he thoroughly understands that the price he pays for glasses is that set by the opticians and the optical houses. The patient must be made to understand that in so paying this high charge

for his spectacles he is subsidizing the optometrist and department-store dispenser, and that the ophthalmologist receives no part of the transaction.

This is an exceedingly difficult thing to do, especially in the smaller communities and by the young ophthalmologist. Many patients will turn to the optometrists, and the physician's income will be greatly cut. However, the ophthalmologist will sleep better at night and enjoy his own company and that of his colleagues more. In time, which will be the shorter the sooner all ophthalmologists get together, the public will know what is going on and the prestige of ophthalmology, grievously hurt by this practice, will rebound to its proper stature.

Why should the ophthalmologist cheapen himself and his great service for the benefit of the optometrist?

DERRICK VAIL.

WILMER RESIDENTS ASSOCIATION

The sixth clinical meeting of the Wilmer Residents Association was held at the Wilmer Ophthalmological Institute, on April 17, 18, and 19, 1947. The individual presentations will, in time, be published and become available to all, but viewing the program as a whole gives an insight into the scope and caliber of the work being done at Wilmer Institute—a view that is not obtained by reading separate papers. Then, too, as publication is often delayed, the program should interest a reader of the JOURNAL, since it indicates where and by whom authoritative investigation is being carried on in relation to particular subjects in which the reader may have special interest.

On the first morning staff rounds were held in conjunction with the medical department, the subjects of "Sarcoidosis" and "Progress of Arteriolar Disease" be-

ing reviewed. Dr. Alan Woods and Dr. Jonas Friedenwald discussed the eye aspects of the cases. Dr. McGee Harvey, Dr. Murray Fisher, and Dr. James Bordley presented the medical aspects. It was indeed enlightening to hear such authorities discourse about these subjects.

The formal eye program followed. A paper on "Ocular Effects of Tridione," a new anticonvulsant, was presented by Dr. Louise Sloan. Approximately 30 percent of patients being treated with tridione (3,5,5-trimethyloxazolidine-2,4-dione) report some degree of glare when going from indoors to brightly lighted outdoors. Because of the glare effect, objects at a distance appear indistinct and colors seem faded. The intensity of symptoms is related to the dosage of the drug. Photophobia begins within 10 days after medication is started, and disappears within a week or two after its discontinuance. The eyes appear normal to examination. In order to understand the photophobia, visual acuity, light discriminatory sense, and flicker phenomena were studied under a variety of illuminations, and it was found that visual acuity and light discriminatory sense were definitely diminished, particularly under conditions of bright illumination; whereas, they were relatively normal with low illumination.

Dr. William Owens, the senior resident, presented cases of "Retrolental Fibroplasia" that had been under observation since birth, and in which the gray opacity behind the lens had been observed in the process of development. He felt that 15 percent of very premature babies, and about $3\frac{1}{2}$ percent of all premature babies would show retrolental fibroplasia. It will be remembered that Dr. Terry found about 12 percent in his series of premature infants. The process is not considered to be related to remnants of the hyaloid system.

"Roentgen Irradiation in the Treatment of Ocular Diseases Characterized by New-Formed Blood Vessels" was the subject of a presentation by Dr. Jack S. Guyton and Dr. Algernon B. Reese. Cases of Eale's disease and diabetic retinitis proliferans were cited, and favorable results were obtained. The X-ray technique was similar to that used in the treatment of retinoblastoma. Special X-ray portals, developed at the Cancer Memorial Hospital in New York, are needed.

Dr. Maumenee presented a paper entitled "Experimental Study of Corneal Transplants," which will be published in the near future.

Dr. John M. McLean showed the technique and examples of "Surgery of the Paretic Inferior Oblique." The muscle is advanced onto the sclera beyond the insertion, in line with the insertion. The results were very satisfactory. Overcorrections can be obtained.

A clinical pathologic conference was conducted by Dr. Snip and Dr. Friedenwald, demonstrating interesting cases that had been seen at the Institute, with pathologic sections.

On the second morning the program began with a paper by Dr. Robert E. Kennedy on "Cystic Malignant Melanoma of the Uvea." "The Role of Rutin and Anticoagulants (Dicumarol) in Retinal Vascular Disease" was the subject of Dr. Angus L. MacLean's paper. "Tantalum Implant for Glaucoma" was discussed and demonstrated by Dr. Malcolm W. Bick.

"A Fixation Light for Testing the Six Cardinal Positions of the Eye" (see the JOURNAL, volume 30, page 611) was demonstrated by Dr. William C. Owens. The apparatus is set up so as to keep the light fixated at the same distance from the eye in all cardinal positions, and allow the examiner's hands to be free for using prisms or for the cover test.

Dr. Jonas Friedenwald presented an

impressive summary of his "Studies of the Physiology, Biochemistry, and Cytopathology of the Cornea in Relation to Injury by Mustard Gas and Allied Agents." Dr. Albert Snell and Dr. John Schilling gave an interesting paper on the "Use of the Anterior Chamber of the Eye in Cancer Research," demonstrating the conditions which are favorable and unfavorable for growth of tissue in the anterior chamber.

Dr. Alan C. Woods spoke on "Chemotherapy in Ocular Tuberculosis." Diasone appeared to have a beneficial effect with immune allergic rabbits, although its clinical trial in the treatment of tuberculosis has yielded disappointing results.

"Injection of Saline into the Eye in Retinal Detachment" was discussed by Dr. Guyton. Drainage holes were made in the sclera over the detachment, and as much as 10 to 20 cc. of saline were injected into the vitreous cavity. This ran out of the drainage holes, and the flow of current tended to force the retina back against the sclera. Coincidentally, a fluid vitreous was created which may, in some cases, allow the retina to settle down. This method of treatment was used only in special cases—when previous operations were unsuccessful, in some aphakic eyes, and when the retina remained elevated after other drainage procedures had been tried.

Dr. Samuel D. McPherson, in his paper on "Sympathetic Ophthalmia," stated that a high percentage of cases of sympathetic ophthalmia show a positive skin test for sensitivity to uveal pigment, as judged by biopsy of the skin at the site of the injection of pigment. Dr. McPherson assumes that the sensitivity reaction allows the etiologic agent to become effective. Sensitivity is also present in cases of trauma and Vogt-Koyanagi syndrome, but in a much lower percentage of cases than in sympathetic ophthalmia. The

sensitivity is not due to the melanin, but to the cellular substance in which the melanin granules appear.

Dr. Charles E. Illiff demonstrated a "New Type of Beta-Ray Applicator." The Burnam-type applicator, previously described by him, utilizes the radon bulb. This bulb is a container filled with the gas, radon, which is a breakdown product of radium. A small window in the covering of the bulb allows a point source of radiation of high intensity which is ideal for occluding blood vessels. Because radon is so difficult to obtain, a new applicator was devised which uses the radium salt spread over the plaquelike end of the applicator. The radon is held in the interstices of the radium salt, and Beta rays are given off as surface fire rather than a point source, as in the Burnam applicator. However, only 50 mg. of radium can be spread on the applicator surface, or the radium itself will act as a filter to lessen the relative ratio of Beta to Gamma rays. The new applicator delivers per unit area only one fourth to one fifth the amount of Beta radiation delivered by the radon bulb of equivalent strength. This limits the use of the new applicator to conditions that can be treated by surface fire. These conditions are vernal conjunctivitis, tuberculous scleritis, and small tumors of the anterior segment. It is not practical to attempt to occlude blood vessels with surface-fire therapy. A special holder is made for the applicator.

On the third morning, the first speaker was Dr. Wilhelm F. Buschke, and his subject was "Experimental Production of Dinitrophenol Cataract in Chickens."

"New Types of Plastic Implants after Enucleation" were demonstrated by Dr. Russell T. Snip. The Guyton implant proved most satisfactory in his hands.

"The Oculocardiac Syndrome: Differential Diagnosis" was the subject of Dr. Frank B. Walsh's presentation. He

stressed the importance of recognition of this syndrome in cases of facial injuries, for, if it were not diagnosed, intracranial lesion might be suspected to be the cause of vagal stimulation, when actually it would be due to injury to the eye.

"The Use of Di-isopropyl Fluorophosphate (D.F.P.) for Glaucoma" was reviewed by Dr. William G. Marr. He stated that when pilocarpine, furmethide, or eserine fail to hold the tension, D.F.P. will not hold it either. Administration of D.F.P. to many patients causes discomfort because of the extreme miosis and ciliary spasm. Some patients have shown sensitivity to peanut oil, the vehicle for D.F.P.

"Use of Furmethide for Glaucoma" (see this JOURNAL, page 999) was discussed by Dr. Ella Uhler Owens. In early cases mecholyl and prostigmine were found to be more satisfactory, and furmethide more effective in late cases. Furmethide is often effective where pilocarpine and eserine have failed, especially in cases with high tension and complications, as after venous closure. Furmethide is now available through Smith, Kline, and French Laboratories, Philadelphia.

The final paper by Dr. Samuel Talbot and Dr. Stephen Kuffler was entitled "Apparatus for Chromatic Stimulation of Single Nerve Fibers of Mammalian Retina. Demonstration of Corneal Potential."

The organization of the program, to interest both the research worker and the practical clinician, and the manner of delivery of every speaker as well as the wealth of information presented were an inspiration to those attending the meeting, and a tribute to the Professor of Ophthalmology of Johns Hopkins University, Dr. Alan C. Woods.

S. RODMAN IRVINE.

OBITUARY

EDWARD COLEMAN ELLETT
(1869-1947)

Edward Coleman Ellett, known affectionately as "The Colonel" to all who attended the meetings of the Ophthalmic societies, died of coronary occlusion in the Atlantic City Hospital on June 7th. After attending the session of the Ameri-

Blackstone Studios, New York

EDWARD COLEMAN ELLETT

can Ophthalmological Society at Hot Springs, Virginia, with Mrs. Ellett, he was stricken on the train en route to the Centennial Celebration of the American Medical Association. Aware for the previous 18 months of the possibility of such an end, his interest in medicine and his specialty drove him to attendance at all meetings, local and national, and to active participation in the discussions. He never failed to contribute some worthwhile suggestion in the field of ophthalmology.

He was born in Memphis, Tennessee, December 18, 1869, the son of Judge Henry T. and Katherine Coleman Ellett. His formal education was received in Memphis private schools, Southwestern Presbyterian University at Clarksville, Tennessee (now Southwestern College at Memphis), and the University of the South at Sewanee, Tennessee. Both schools at later dates conferred upon him honorary degrees, Southwestern College the degree of doctor of law, in June, 1942, and the University of the South, the degree of doctor of science, in June, 1943. Dr. Ellett studied medicine at the University of Pennsylvania from which he received his doctor-of-medicine degree in 1891 and from which he was graduated as top man in the class. An internship at St. Agnes Hospital and a residency at Wills Eye Hospital, Philadelphia, prepared him for a long life of service in his home community. This service was acknowledged by his colleagues with a testimonial dinner in May, 1943, to celebrate his 50th year of active practice of medicine in Memphis.

In 1896, he was married to Nina Polk Martin and with her, last year, celebrated the 50th anniversary of a marriage which has been a symbol of love and devotion. Their mutual interest allowed them to enjoy many things in common, especially travel. Almost every summer they went to Europe, usually stopping in southern France, which both of them loved so well. They travelled in South America several times and made numerous trips to Havana. Wherever they might be, Dr. Ellett sought out the ophthalmologists, making firm friendships, which have endured, and picking up any new procedures and techniques which he could fit into his own surgical program.

"The Colonel" was a great teacher. For 16 years he was Professor of Ophthalmology at the University of Tennessee

Medical School, but his main interest was in graduate teaching in ophthalmology. In this field he had many associates in his private office, who later branched off into their own practices in Memphis and other cities, continuing successfully the precepts he taught so well. At his own expressed wish 11 of them were honored by being asked to carry him to his last resting place. His interest and regard for them were maintained until the very end.

Dr. Ellett's interests were mainly in clinical ophthalmology and his papers were based, as a rule, on the experiences of actual practice. Too numerous to record, there is scarcely a one which cannot yet be read with profit. He attended medical meetings religiously and was an active participant in discussions, disclosing a tolerant attitude toward the opinions of others but being firm in his own convictions. His tall, spare, and erect figure, was a familiar sight whenever the Academy, the A.O.S., or the Section on Ophthalmology was in session. During intermissions he was usually engaged in conversation with someone who had a problem to solve. Or, he was passing on the most recent anecdote which had come to his attention, for he loved a good story and told it well.

He delighted in the success of those men on whom he had exercised some influence through hospital connections, military life, or acquaintance at ophthalmic meetings. No request for advice was ever refused and, because of his long years of experience and scientific training, he usually had some worthwhile suggestion to offer. As a consultant, he was understanding and kindly and had the ability to alter a course of therapy without destroying the patient's confidence in his physician. His mind was always active and alert. If a certain form of treatment proved unavailing, he never hesitated to change to another even though the sug-

gestion might come from the most recent of his associates. He respected the dignity of man and was always willing to concede the merit of an idea and place proper credit where it was due.

I well remember the incidents of our first meeting, 21 years ago, and the conversations relative to the long and pleasant association which we enjoyed through all those years. After satisfying ourselves that such an association might be mutually agreeable, the question arose as to the need of a written contract. "The Colonel's" remarks were, "Doctor, I don't think we need one. An association in the practice of medicine is like a marriage. It will either work or it won't and if it won't work, a written contract isn't going to make it do so." It was on such terms that our association persisted and our relations were more like those of father to son than as senior to junior partner.

One idolizes and idealizes someone he loves, and the tendency is to allow sentiment to gloss over such defects as become apparent when the initial enthusiasm of a new association tends to wane. I never had cause to regret the good fortune which brought me to an association with Dr. Ellett. During all those years, there was never a serious difference of opinion, although one's opinion was frequently required; and at the close of 21 years of daily contact my love and respect for Dr. Ellett were exactly the same as when formed at the initial meeting. Dr. Ellett's professional ability and integrity, his innate courtesy, his genuine kindness and interest in the troubles of others always made him a tower of strength to his family and his friends in moments of personal distress.

His professional attainments and honors were most numerous. He belonged to every local, state, and national medical organization both in general medicine and his specialty. He had served as president

of the Memphis and Shelby County Medical Society, the Memphis Society of Ophthalmology and Otolaryngology, the Tennessee Academy of Ophthalmology and Otolaryngology, the American Academy of Ophthalmology and Otolaryngology, the American Board of Ophthalmology, and the American Ophthalmological Society, and was chairman of the Section on Ophthalmology of the American Medical Association and vice-president of the Southern Medical Association and the National Society for the Prevention of Blindness. He had served as an associate editor of the AMERICAN JOURNAL OF OPHTHALMOLOGY.

The Academy honored him with the Award of Merit; the Board, with a testimonial silver tray; and the National Society for the Prevention of Blindness, in conjunction with the St. Louis Society for the Blind, awarded him the Leslie Dana Medal. The Memphis and Shelby County Medical Society and the Memphis Society of Ophthalmology and Otolaryngology honored him on separate occasions with testimonial dinners.

During World War I, Dr. Ellett commanded Base Hospital 115 at Vichy, France, for which he received a citation for meritorious service. While in the Medical Corps, he was made a full Colonel, a title by which he was known the rest of his life.

Dr. Ellett was a member of Calvary Episcopal Church.

His fraternal orders were Kappa Sigma and Phi Alpha Sigma, and he belonged to the Memphis Country Club and the University Club of Memphis. As a member of the Waponoca Club, he was able to satisfy his enthusiasm for golf, tennis, and hunting—sports which he thoroughly enjoyed to the very last. "The Colonel" had an inner drive toward perfection which motivated his every action. He was constantly learning. At 60 years of age, he

took lessons to improve his Spanish and his backhand in tennis, with considerable success in both efforts. He was always willing to impart any such knowledge to those who desired it. Never will I forget the occasion, when my golf ball was lying against a fairway bunker and I insisted, with the usual result, on using the wrong club to gain distance. On my desk the following morning was an illustrated book on golf, opened to the page showing the exact situation of the previous day and demonstrating that a nine iron was the only club of choice. A good shot, Dr. Ellett enjoyed gunning afield for quail and pheasant and over the water for ducks and geese, and some of his most pleasant reminiscences were of days in the open.

Despite his love of sports and interest in medical affairs, Dr. Ellett's devotion to his patients and their devotion to him was inspiring. No complaint was too trivial to be heard to the end and no one suffered more than he did if a case of failing vision could not be halted or if sight could not be restored. His interest in the welfare of his patients was sincere and sustained, and regardless of the condition of his own health, he somehow always had time for those requiring his services. He was never too busy to stop to listen to a disconcerting problem or to have a look at the patient who was not doing well. Always there was some beneficial suggestion or the kindly assurance that all that was possible was being done.

A deft surgeon, Dr. Ellett pioneered in this country many of the surgical techniques that are now standard procedures, such as intracapsular cataract extraction with the corneoscleral suture, the Elliott corneoscleral trephining, the diathermy treatment of retinal separation, and plastic dacryocystorhinostomy. He was the center of a large audience in the operating theatre and never failed to give his most masterly performance in the presence of

on-lookers. He maintained his steady and accurate hand to the very last and, although restricting his office practice to consultation only, continued his intraocular surgery daily until the end. It was always an inspiration to watch him at work for there was a minimum of action, everything being done in the simplest and most direct way to achieve the desired result. His techniques and teachings were indelibly impressed on a large number of associates and residents, and he will live on in the works of those who were his students.

Wise counsellor and staunch friend, it seems strange not to hear his light footfall and feel his firm hand on one's shoulder as he comes to the examining room to impart a bit of advice or some news of mutual interest. But his influence will endure and mold the lives of all who knew him.

RALPH O. RYCHENER.

BOOK REVIEWS

A TREATISE ON GONIOSCOPY. By Manuel Uribe Troncoso, M.D. Philadelphia 3, Pennsylvania, F. A. Davis Company, 1947. 318 pages, 117 illustrations (35 in color), index, and bibliography. Price \$10.00.

The important pioneer work on this subject and the instrumentation devised by the author are too well known to need comment. This book represents the crowning achievement of a lifetime devoted to the study of the angle of the anterior chamber by Dr. Troncoso. It is clearly written and illustrated and is a work of great significance in ophthalmology.

Gonioscopy, or the art of examining and interpreting the conditions seen in the anterior chamber of the living subject, has had a difficult evolution. It has

taken many years to attract the attention that it deserves, and it is only in recent time that the procedure is becoming more popular. Part of this delay has been the somewhat time consuming and difficult technique hitherto necessary. In these days of overburdened practices, the ophthalmologist hesitates to devote any time to a study that seemed to offer so little reward to the patient or to himself in adding to the judgment of the case. More and more information appearing in our literature is coming from authorities whom we have learned to respect and trust, and more and more converts are being made. Improvements in the instrumentation and in the technique, owing in very large measure to Dr. Troncoso's scientific outlook and acumen, have made the procedure much less formidable and time consuming. Gonioscopy is not yet as easily done as are slitlamp microscopy or ophthalmoscopy, but it is rapidly approaching these maneuvers in ease of accomplishment and clinical importance.

The author's timely book sets forth in clear terms the interpretation of the various findings in the anterior chamber in health and disease. Attention is directed to the importance of a visual study of the angle in various kinds of glaucoma, as an aid particularly in the choice of an operation or in the analysis of its failure. Inflammatory conditions, tumors, foreign bodies, congenital anomalies, and changes in age affecting this area are a part of gonioscopy, as developed by the author. Prof. Ida Mann has written, especially for this book, a chapter on "Development of the Angle of the Anterior Chamber in the Human Eye," which is a classic.

The publishers have done a splendid

job. The book is beautifully printed, and the illustrations, particularly the colored ones, are to be commended. It is a pleasure to possess this book and to use it, and it is inconceivable that any ophthalmologist would deny himself this pleasure, especially in a world so full of woe.

DERRICK VAIL.

UEBER NICHT HYPOPHYSÄRE CHIASMASYNDROME. By M. Gil. Espinosa (Madrid). Supplement of *Ophthalmologica*. Basel, Switzerland, S. Karger, 1946. 60 pages, 15 illustrations, paperbound. Price 7.50 Swiss francs.

This well-written monograph adequately discusses what is known as the Chiasmal Syndrome, a term coined by Cushing, who presented a paper with this title before the International Congress of Ophthalmology in Amsterdam, in 1929. (*Archives of Ophthalmology*, 1930, volume 3, pages 505 and 704.)

After a description of the signs and symptoms of a lesion in the chiasmal area, the author discusses the nature of the lesions and the differential diagnostic points of significance. There is thus presented a short analysis of hypophyseal adenoma, craniopharyngioma, tumors of the IIIrd ventricle and of the infundibulum, arachnoiditis opticochiasmatica, glioma of the chiasm, aneurysm, granuloma, suprasellar cholesteatoma, meningioma of the base of the skull, and indirect compression of the chiasm. However, not much has been added to the subject so ably expressed by Dr. Cushing and other American authors.

DERRICK VAIL.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

CORNEA AND SCLERA

Fuchs, Adalbert. The influence of general metabolic and nutritional disturbances upon the resistance of the cornea. *Amer. Jour. Ophth.*, 1947, v. 30, June, pp. 721-727. (5 references.)

Harbert, F., and McPherson, S. D. Scleral necrosis in periarteritis nodosa. *Amer. Jour. Ophth.*, 1947, v. 30, June, pp. 727-732. (6 figures, 11 references.)

Morone, G. Researches on the sensibility of the transplanted corneal discs in keratoplasty. *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 72, May, pp. 279-297.

The author presents 11 cases of keratoplasty in which the sensibility of the cornea with respect to touch, temperature, and pain was tested with the esthesiometer and technique of Puglisi-Duranti. The transplanted disc, whether it becomes opaque or remains transparent and unvascularized, may acquire a sensibility of its own after the lapse of a year. Such sensibility is always inferior to that of normal cornea, and the cornea of the host is often

hypesthetic as well. A warm stimulus is usually well perceived as such. The sensibility of the transplants seems to depend but little on the nature of the postoperative course, on the age and sex of patient and donor, and on the width of the cicatricial band around the transplant.

The anatomy of the innervation of the cornea and the physiology of its sensibility are reviewed.

Harry K. Messenger.

Seidenari, R. Histologic aspects of refrigerated corneal epithelium. *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 72, May, 298-316.

A detailed study is presented of the histologic changes that occur in the epithelium and in Bowman's membrane of refrigerated and nonrefrigerated human corneal tissue, specimens of which were examined at $\frac{1}{2}$, 2, 5, 10, 24, 36, and 48 hours after death. (The article is accompanied by a complete series of comparative photomicrographs.) The refrigerated corneal tissue was kept in small glass vessels surrounded by finely

chopped ice; the controls were kept at room temperature.

Exfoliation occurred in both instances, but sooner and more rapidly in the nonrefrigerated cornea, whereas the histochemical properties of the cytoplasm and nuclei of the cells of the basal layer remained nearly normal for 48 hours in the refrigerated tissue. Likewise the refrigerated tissue remained acidophilic much longer. There was no essential difference in the behavior of Bowman's membrane.

Harry K. Messenger.

Seidenari, R. **Histologic aspects of refrigerated corneal parenchyma and endothelium.** *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 72, June, pp. 363-375.

A comparative histologic study was made of the condition of refrigerated and nonrefrigerated corneas at intervals of one half to 48 hours after death. The nonrefrigerated corneas were kept at room temperature; the others were refrigerated in a small glass container surrounded by melting ice. It was found that in the refrigerated specimens the thickness of the cornea is less than in the nonrefrigerated, and the thickness of Descemet's membrane is practically unchanged. In the refrigerated group the normal acidophilic properties of the tissues are retained even after 48 hours, whereas they disappear by the fifth hour in preparations not exposed to the action of cold. Likewise the individuality of the lamellae is preserved even after 48 hours of refrigeration, whereas dissociation begins four hours after death in the nonrefrigerated specimens. Harry K. Messenger.

Senigaglia, A. **The syndrome of Van Der Hoeve with psychopathy.** *Riv. Oto-Neuro-Oft.*, 1946, v. 21, May-Aug., pp. 236-244.

A woman 39 years of age with negative family history, had slight depressive psychosis, marked tendency to fractures after slight traumas, deafness which became manifested when she was 30 years of age, and blue scleras. The symptomatology and pathogenesis are discussed. (2 figures, bibliography.)

Melchiorre Lombardo.

Stenstam, Toivo. **On the occurrence of keratoconjunctivitis sicca in cases of rhenmatoid arthritis.** *Acta Med. Scandinav.*, 1947, v. 127, no. 1-2, pp. 130-148.

The material for the study was provided by 495 hospital patients with rheumatoid arthritis ranging from 12 to 55 years of age. Sixty of the 495 cases of arthritis were cases of acute rheumatic fever. Forty-seven of the patients had keratoconjunctivitis sicca. Only one of the 47 occurred in those suffering from rheumatic fever. Because of the joint symptoms these patients attended the rheumatological clinic more frequently than the eye clinic and this fact probably explains the rare occurrence of this eye disease in the out-patient visitors at the eye clinic. Sjogren found one case of keratoconjunctivitis sicca in every 2,000 patients with disease of the eye.

Neurological and clinical studies brought out nothing of importance. Males and females were practically equally affected. The Wassermann reaction was negative in all the patients with keratoconjunctivitis sicca; tuberculin tests were positive in as many cases of arthritis with this disease as without. All these facts make it unlikely that the arthritis and laboratory findings are typical of or are a part of this ocular condition.

The right eye, staphylomatous, had been enucleated, and the left eye had been blind for 42 years by reason of a large central leucoma, adherent in the lower part. Optical iridectomy at the 12 o'clock position had produced little improvement. Fortunately the more or less quadrate staphyloma was surrounded by a transparent zone. The keratoplasty was performed on May 20, 1946, using Castroviejo's technique. The continuous suture was removed after 12 days, and the eye was left uncovered after 16 days. The patient was discharged from the hospital after six weeks, with corrected vision of 0.6, and two months later the glasses were changed with further improvement of vision to 0.8. A still further slight change on January 18, 1947, gave vision of 0.9.

Haefeli, W. **The permeability of the blood-aqueous barrier for fluorescein.** Ophthalmologica, 1946, v. 112, Oct.-Nov., pp. 226-254.

Amsler and Huber (Ophthalmologica, 1946, v. 111, p. 156) have devised a simple optical method for the quantitative determination of fluorescein in the aqueous in situ. After the intravenous injection of 2 c.c. of a 10-percent solution of fluorescein sodium, the eye is observed with slitlamp and corneal microscope for the appearance of a green tinge of the aqueous, the intensity of which is measured by dimming, by means of a rheostat, the slitlamp light to the point of disappearance of the green fluorescence. At this extinction point, the intensity of the electric circuit feeding the lamp is inversely proportional to the concentration of fluorescein in the aqueous. With this method the passage of fluorescein into and out of the aqueous has been studied quantitatively on a large number of individuals with normal eyes. The results are presented statistically.

Under the conditions described in the foregoing, fluorescein becomes visible in the aqueous two to four minutes after the injection. The highest fluorescein concentration is reached 25 to 30 minutes after the injection. Children under 15 years of age show increased permeability to fluorescein. Two eyes of the same individual usually behave similarly as far as the passage of fluorescein into and out of the eyes is concerned. After reaching the peak, the fluorescein concentration in the aqueous diminishes very gradually, much more slowly than in the blood. Repeated fluorescein tests on the same individual show very slight variations. In none of the tests on normal eyes was there any optically demonstrable increase in the protein content of the aqueous during the fluorescein experiment.

Benner, R. **Diathermy puncture of the ciliary body.** *Ann. d'Ocul.*, 1947, v. 180, Feb., pp. 89-102.

Based on 44 operations performed on 28 eyes, the detailed results of the diathermic operation of Vogt are tabulated. Approximately 75 percent of

these operations followed other surgical procedures. After conjunctival and retrobulbar anesthesia, and dissection of the conjunctiva and subconjunctiva, 100 to 300 perforating and non-perforating punctures are made in the sclera, 3 to 4 mm. behind the limbus and encircling the globe. These are best accomplished with a shouldered needle 0.5 mm. long, about 0.1 mm. in diameter and with a current of 60 to 80 milliamperes.

The author confirms the experiences of Vogt, Thiel and others that this procedure is best adapted to eyes in which the risks of other surgery are high. It is less applicable to acute and primary glaucomas than to congenital, and glaucomas secondary to iritis, aphakia, and trauma. Sympathetic ophthalmia is a possible complication which the author did not encounter. (7 references.)

Chas. A. Bahn.

Gallois, J. **Chronic glaucoma with minimal elective vasodilation.** *Ann. d'Ocul.*, 1947, v. 180, Jan., pp. 20-28.

In advanced primary glaucoma capillary degeneration is frequent, both in the eye and other tissues such as the nail bed, and is often accompanied by angiospasm and other disorders of capillary permeability. Ocular hypertension may be the result of vascular noninflammatory malformations such as nevi and arterio-venous aneurysms and of low grade inflammatory and degenerative reactions especially those involving the choroidal veins. Retinal endo- and periphlebitis are not infrequently observed in sections of eyes with primary glaucoma. Stasis, especially in the choroidal veins, frequently complicates bodily atherosclerosis. Stasis in the retinal veins is more passive, but both are aggravated by ar-

terial or capillary compression. Vasodilating substances in very small doses tend to reduce venous stasis and thereby potentially reduce intraocular tension. In larger doses they tend to increase intraocular tension. Among the vasodilating drugs thus experimentally used in glaucoma are calcium chloride, magnesium sulphite, nicotinic acid and benzyimidazoline. Based upon an apparently large number of cases and years of study the following test is proposed to determine the advisability of surgical intervention in individual patients with primary glaucoma: 30 mg. of nicotinic acid or 25 mg. of benzyl-imidazoline is slowly injected intravenously, and the tonometric tension is measured every 15 minutes during one hour. No miotic is used before or after the injection. In unfavorable cases which usually include the acute primary and secondary hemorrhagic and long standing degenerating glaucomas, the tension is stationary or somewhat increased, which means that miotic treatment alone will probably not control the ocular hypertension. If the intraocular tension is lowered as it was in 14 of 18 cases observed, the continuance of proper nonsurgical treatment should be considered.

Chas. A. Bahn.

O'Brien, C. S. Surgical treatment of primary glaucoma. *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 134-138.

Iridectomy is preferred for the relief of acute block of the anterior chamber in cases of narrow-angle glaucoma. The operation is usually successful if the tension can be reduced to normal with miotics or if the acute attack is not of more than three days duration. An ab externo incision is preferable. Cyclo-

dialysis is most successful in cases of early chronic wide-angle glaucoma and the secondary glaucoma which follows cataract extraction. If almost half the circumference is dialyzed the results are much better. Of the operations which open an extraocular drainage channel, the author prefers the sclerecto-iridectomy of Lagrange. The technique for these operations is described.

Torres Estrada, Antonio. Indications for iridectomy in hemicycodialysis. *Bol. del Hosp. Oft. de Ntra. Sra. de la Luz*, 1946, Nov.-Dec., 1947, Jan.-Feb., pp. 237-244.

Iridectomy may be performed prior to the hemicycodialysis, combined with it, or after its execution. The author favors previous iridectomy in all the

congestive forms of the disease, the hemicyclodialysis being performed a few weeks later, when the eye has become quiet. When the two operations are done at the same sitting, iridectomy is done after introducing the spatula, and disinsertion of the ciliary body is the final step. W. H. Crisp.

Weekers, L., and Weekers, R. Technique of nonperforating cyclodiathermy. *Ann. d'Ocul.*, 1947, v. 180, Feb., pp. 76-88.

Diathermy produces uveal vasodilatation, autonomic nervous changes, and specific biochemical actions and thereby potentially reduces ocular hypertension. If properly used, the nonperforating technique is as efficient and far less dangerous than the perforating. The authors prefer a curved electrode with a round tip and an insulated shoulder to facilitate the proper pressure. After local anesthesia, the retrobulbar injection of 4-per cent procaine solution is followed by one c.c. of 40-per cent alcohol. Twelve to 20 applications of 15 seconds' each are made directly on the conjunctiva and encircling the eyeball 7 to 8 mm. posterior to the limbus. The resistance is previously so regulated that the conjunctival temperature is approximately 30° C. at the instant of application and 90° C. in five seconds. The procedure is not painful, no bandage is used postoperatively and only normal salt solution is employed as an irrigating fluid. Hypotension usually begins after a few hours, though occasionally a transient but not important hypertensive phase occurs. The postoperative reaction is usually slight and after a month only a slight focal chorioretinal atrophy exists with pigment dispersion. In one of the cases reported, the

operation was successfully repeated after eight months. This procedure is considered as efficient and less difficult and dangerous than operations whose success depends on opening the eyeball and delicate dissections, especially in the glaucomatous eye. (8 references.)

Chas. A. Bahn.

Weekers, R. Incomplete glaucoma. *Ann. d'Ocul.*, 1947, v. 180, Jan., pp. 10-19.

Primary glaucoma is characterized by three cardinal symptoms: ocular hypertension, excavation of the disc, and visual defects, peripheral and central which are correlated with vascular disease in the uvea, the disc and the retina respectively. In primary glaucoma, these three locations are frequently not equally involved and therefore the cardinal symptoms may vary widely. Any one or two of the three cardinal symptoms may indicate an advanced stage when the other symptoms are practically absent. This the author terms incomplete glaucoma, which may be monosymptomatic, or bisymptomatic. One eye may be monosymptomatic and the other bisymptomatic. Monosymptomatic glaucoma may exist for years as such, but usually is an early stage of the bisymptomatic type. The monosymptomatic form includes glaucomatous types of excavation with ocular hypertension of 25 mm. Hg or less and practically no visual defects. Such is the lacunar degeneration of the disc described by Schnabel. Ultimately this type become bisymptomatic. Intraocular hypertension without disc excavation or visual defects is usually the initial stage of the bisymptomatic type. Ocular hypertension alone may exist for a number of years and

does not call for surgical intervention. Ocular hypertension is better tolerated in those with bodily arterial hypertension. Sudden lowering of the arterial hypertension is usually followed by aggravation of the glaucoma. Intraocular hypertension is better tolerated if the minimal arterial retinal tension is elevated. Glaucomas with low ocular tensions but with characteristic campimetric defects are more frequent in those with low retinal arterial tension. The appearance of spontaneous arterial pulsation suggests that the retina is suffering from ischemia. Defective vision with apparently normal ocular tension and disc excavation, but with arciform scotoma may represent the more or less prolonged monsymptomatic stage of an ultimately bisymptomatic glaucoma. In primary glaucoma defective vision is caused by retinal ischemia from arteriolar spasm or from extravascular pressure either in the retina proper or at the disc. Retinal damage caused by the ischemia primarily involves the second and third neurones, with typical defects in the visual fields. Defective vision with characteristic disc excavation may long coexist with ocular tension below 25 mm. Hg. Prolonged defective vision with intraocular hypertension but without characteristic disc excavation is rare. Disc excavation and hypertension without visual defect is relatively frequent, though with very small targets pathologic neuroscotoma may be found.

CRYSTALLINE LENS

Gardilic, A. **Extraction of the dislocated lens after Jess-Lacarrère.** Oph-

thalmologica, v. 112, Oct.-Nov., pp. 255-266.

Independently of each other, Jess and Lacarrère devised a method for the extraction of dislocated lense (lying at the bottom of the vitreous) by spearing and lifting them out of the eye with a needle-shaped electrocoagulation electrode.

Gardilic has modified the method as follows. After dissecting a fornix-based conjunctival flap, the incision is started by making a limbic groove into which two corneoscleral sutures of the McLean type are inserted. Through a tiny separate groove at the three-o'clock position in the left eye and nine in the right the needle electrode is introduced into the eye. Guided by the ophthalmoscope, or, in the case of a cloudy vitreous, by a transilluminator applied to the inferior part of the sclera, the electrode is brought in contact with the lens, the needle inserted into it and the coagulating current turned on for two seconds. By careful manipulation of the handle of the electrode, the surgeon makes sure that the lens is following the movements of the needle. The limbic incision is completed with a Graefe knife and extended, with scissors, right up to the previously inserted needle electrode. The lens is extracted by manipulation of the needle electrode and a Weber loop, to depress the posterior wound lip. The author reports one success and one failure.

Some of the cardinal principles of the

CYCLODIALYSIS, MULTIPLE OR SINGLE, WITH AIR INJECTION

AN OPERATIVE TECHNIQUE FOR CHRONIC GLAUCOMA*

OTTO BARKAN, M.D.

San Francisco

The objective of this procedure is to create a larger dialysis with less trauma than is possible with the ordinary technique of cyclodialysis and to control hemorrhage, thus promoting the formation of a cleft of sufficient size which is permanent. Multiple (or single) cyclodialysis combined with air injection according to the technique described in the following pages has been in my experience a safer and more effective operation than a single cyclodialysis according to the usual method.

The results reported are based on operations performed on 83 eyes. Primary glaucoma was present in 70 eyes; pressure was normalized in 63. In 7 eyes, the results were unsuccessful. Analysis shows that in the eyes afflicted with primary glaucoma, 57 were of the wide-angle type. Tension was normalized in 50 of these, in 41 without the use of miotics; in 9 miotics were required. Of 13 cases of the primary, narrow-angle type of glaucoma with peripheral adhesions (chronic congestive glaucoma), all were normalized; 12 without the use of miotics, and one with miotics.

Of 13 cases of secondary glaucoma, five were normalized without miotics and one with miotics. Seven of these cases

showed unsuccessful results. Since these seven cases were complicated by venous thrombosis, siderosis, cyclitis, and aphakia after unsuccessful trephination, the surgical prognosis would have been extremely poor for any operation.

In judging results, the condition was considered arrested if function was preserved and intraocular pressure remained less than 35 mm. Hg (McLean) for at least one year after the operation. In most of the cases analysed in this report, 3 to 10 years have elapsed since operation. All reported cases were from private practice and were, therefore, well adapted to detailed analysis.

INDICATIONS FOR CYCLODIALYSIS

The effectiveness of cyclodialysis is contingent upon its application to the case in which it is indicated.

It is suggested that the ineffectiveness of present-day operations for chronic glaucoma may be due in some measure to improper choice of the kind of operation to suit the individual case. Improper selection would appear to be due to lack of knowledge of the local mechanical, or the pathologic-anatomic cause of increased pressure in the individual case and to absence of classification of the lesion. Knowledge of these factors would permit a preoperative etiologic differentiation of cases from a surgical point of

* Read at the 75th annual session of the Section on Ophthalmology of the California Medical Association in Los Angeles on May 8, 1946.

view and would facilitate a more rational selection of operation on a causal basis.¹

In previous communications a pathologic-anatomic classification was suggested,^{1,2} in which cases of primary glaucoma were divided into the narrow-angle (or iris-block) and wide-angle types. This has proved a useful guide to the selection of operation and has, in my experience, given better assurance for the effectiveness of the respective operations.

According to this classification, cyclodialysis was used in primary glaucoma in cases of the wide-angle type and in those cases of the narrow-angle type in which a large part of the angle was permanently closed by adhesions. In the wide-angle type, the operation may be used as an alternative to the external filtering operations. In the narrow-angle type, it is suggested that cases presenting peripheral adhesions (late stage of the narrow-angle type, commonly called chronic congestive glaucoma) are particularly amenable to cyclodialysis, since there appears to be little tendency for readherence in the region in which the angle was previously closed by adhesions. For similar reasons it appears that repeated cyclodialysis in the area of a previous cyclodialysis, in which the cleft has become closed by adhesions, is often effective.

A high degree of pressure has not contraindicated the use of this procedure. Although it is assumed that an effort will be made preoperatively to convert a congestive phase into a noncongestive one, congestion does not preclude the operation. The modified procedure of cyclodialysis described in this article appears to be effective under both congestive and noncongestive conditions. Indeed, in cases of the narrow-angle type, in which the angle is closed by adhesions and which are in a highly congestive stage,

cyclodialysis combined with air injection would seem to be the operation of choice to the exclusion of other operations. In this variety and stage of glaucoma, trephination, iridencleisis, and iridectomy are known to be generally ineffective and associated with considerable hazards.

In a series of 13 such eyes operated on according to the technique described, cyclodialysis has been successful in all 13 eyes for periods varying from 1 to 10 years. In one case which had run a congestive course for several weeks with tension of 70 mm. Hg (McLean) both eyes were successfully operated on, and tension was normalized until the death of the patient, 14 months later. Histologic examination showed peripheral synechiae extending throughout the circumference of the angle of both eyes, except in the region of the operation. Here the adhesions had been separated and the angle opened. A cleft leading into the suprachoroidal space was present.*

Cyclodialysis may be indicated in cases in which other operations for glaucoma have failed. In some desperate cases in which the anterior chamber is almost or completely absent, it may be used to advantage combined with iridectomy, according to Wheeler.³ In secondary glaucoma, ophthalmic experience has indicated that cyclodialysis is especially effective in cases of aphakia and luxation of the lens.

Cyclodialysis is relatively contraindicated, in my experience, in cases of primary narrow-angle glaucoma *unless* adhesions have formed in the angle.⁵ When cases of this type have run a noncongestive course, as they often do for many years, they have usually been diagnosed—with cases of the wide-angle type—as chronic simple glaucoma and have con-

* A report of the histologic findings in this case will be published in the near future.

sequently been operated on by cyclodialysis or by an external filtering operation. In narrow-angle glaucoma, however, the crowded anatomic conditions in the angle and the relatively increased vitreous pressure, which tends to propel parts forward and to press the ciliary body against its base, encourages closure of the cleft made by the cyclodialysis. On the basis of clinical experience and post-operative gonioscopic studies, iridectomy⁴ (in modified form) appears to give better results. It has been effective in the large majority of cases presenting the narrow-angle type of glaucoma before adhesions have formed in the angle.

SUMMARY

Cyclodialysis combined with air injection is indicated in primary glaucoma of the wide-angle type. It appears to be the operation of choice in cases of narrow-angle glaucoma with peripheral adhesions and in certain varieties of secondary glaucoma. It may be used to advantage on eyes in which other glaucoma operations have failed.

ACTION OF CYCLODIALYSIS

Gonioscopic studies^{5, 6} have shown that the successful action of cyclodialysis depends upon the formation of a permanent separation or cleft between the ciliary body and its attachment. This is confirmed by the histologic findings in a single case of Elschmig,⁷ and in two eyes in the present series which were successfully dialysed and came to section one year after operation. The role of the cleft formation has been confirmed by Clarke,⁸ Sugar,⁹ and others.

It is assumed that the aqueous passes through the cyclodialysis cleft into the suprachoroidal space where it is absorbed. The assumption is confirmed clinically by several cases in this series, in which an acute rise in pressure fol-

lowed a gonioscopically demonstrable, sudden closure of the cleft several years after the operation. Reopening of the cleft by miotics resulted in a sudden drop of pressure to the previous normal.

Gradual closure of the cleft, which has been the cause of the frequent lack of permanent results of cyclodialysis, is shown by gonioscopic studies⁵ to be due to: (1) Insufficient extent of the original dialysis. (2) Operative trauma in the region of the cleft, which causes adhesions. (3) Hemorrhage into the anterior chamber (at the time of operation or during the first week of convalescence) which promotes readherence of the ciliary body. Hemorrhage has been a common clinical experience, and its influence on closure of the cleft is well known. A direct relationship may be remarked between hemorrhage into the anterior chamber and readherence of the iris root, not only by its incidence but also by actual observation in the individual case of the process of readherence along the line of the organizing blood clot.

AIR INJECTION IN CYCLODIALYSIS

In 1938, the writer injected air into the sealed anterior chamber with the intention of deepening it and widening the cleft by pushing the iris posteriorly. Immediately following injection, a slight hemorrhage into the chamber, such as commonly occurs in cyclodialysis, was seen to stop. After evacuation of the air from the chamber, no further bleeding occurred.

Furthermore, it was observed that the chamber angle had become image forming, evidently due to the different refractive index of air from aqueous. As a result, the cleft and its widening could be seen by direct observation without the use of a prismatic contact glass; the size or sufficiency of the cleft could often be determined at the time of operation.

The observations made at that time indicated that air injection might become a valuable aid in stopping and in preventing hemorrhage during cyclodialysis; that it might help in determining the sufficiency of the cleft immediately subsequent to operation; and finally that it might be used to maintain the patency of the cleft.

It was next observed, in some cases, that after several minutes and under certain conditions, there developed a progressive rise in intraocular pressure, evidently as the result of air blocking the free circulation of aqueous, thus producing a secondary glaucoma. When this condition occurred, there was a sufficient quantity of air under pressure to produce seclusion of the pupil, which in some cases was combined with obstruction of the angle. In view of this danger, it became evident that only a limited quantity of air could be allowed to remain post-operatively in the anterior chamber to maintain the cleft opening. Further observations on this subject will be published in a succeeding paper.

Various developments and experiences with air injection in a series of over 83 eyes operated on by cyclodialysis since 1938 have confirmed these observations. Air injection has consistently proved effective in stopping and in preventing hemorrhage in all cases of cyclodialysis in which it has been promptly used.*

In the procedure of air injection for single and multiple cyclodialysis, air, followed by physiologic saline solution if desired, is injected into the sealed anterior chamber. Both the scleral incision for the injection of air and the corneal puncture for the injection of saline are made in an oblique direction in order that they may act as valve or trap-door aper-

tures, which permit ingress but prevent egress of air or fluid except when this is desired. The anterior chamber is thus air and watertight as regards its contents.

The anterior chamber need not necessarily be completely filled with air. A bubble of air, which does not entirely fill the chamber and does not increase the pressure, will act as an adequate cushion to prevent excessive hemorrhage, keep the cleft free of blood, and, perhaps, help by its presence to keep the opposing surfaces apart in many cases. In cases in which hemorrhage threatens, however, it appears advisable to inject air under pressure, thus filling the entire chamber.

The amount of air pressure exerted on the inner walls of the anterior chamber can be controlled according to need. The air may be regarded as an adjustable internal tourniquet. After a few minutes of increased air pressure, when the danger of hemorrhage is past, a part of the air may be allowed to escape through an oblique puncture incision made in the cornea with a Graefe knife, in order to obtain a valve closure; or the air released may be replaced if desired by physiologic saline solution under pressure. When saline solution is used, the increased intraocular pressure returns to normal within 5 to 10 minutes. Evidently the excess solution is carried off through the physiologic channels of outflow and possibly also through the cyclodialysis cleft.

Air injected into the anterior chamber prevents primary hemorrhage during and immediately following operation by raising intraocular pressure. The presence of air and saline solution in the anterior chamber also neutralizes the suction action of the cornea which might, otherwise, encourage bleeding into the chamber. Later when the excess air is removed, the substitution of physiologic saline solution prevents secondary hem-

* The hemostatic action of air injected during cyclodialysis has recently been noted by Randolph.²⁰

orrhage into the retina or vitreous, such as is caused occasionally by too sudden a reduction of pressure following cyclodialysis in elderly patients with sclerotic blood vessels. It does not, however, appear to discourage the late secondary hemorrhages into the anterior chamber which may occur during the first week following operation.

MULTIPLE CYCLODIALYSIS

Restoration of the anterior chamber by air injection immediately following a cyclodialysis makes it possible to perform

posure of the sclera in both upper and lower quadrants, a tightly wound applicator which has been dipped in adrenalin (1:1,000) may be pressed against the areas of the sclera in which the incisions are to be made. Episcleral vessels may be obliterated by cauterization with the end of a strabismus hook which has been heated in an alcohol flame. The posterior conjunctival flap is retracted by means of six 5-0, atraumatic, single-armed sutures of black silk which are attached under some tension to the face mask by means of hemostatic forceps.

Fig. 1 (Barkan), A curved conjunctival flap, 10 mm. in length, is formed extending from the 6- to 12-o'clock positions. The posterior flap is retracted by means of six 5-0, atraumatic, single-armed sutures of black silk which are attached under some tension to the face mask by means of hemostatic forceps.

a second cyclodialysis. By creating two moderate-sized dialyses at the same sitting, it is possible to obtain more consistently an adequate separation of the iris root with less trauma than by a single large dialysis. It is also possible to avoid major blood vessels which are situated in the horizontal meridian.

TECHNIQUE

Preoperatively, extreme miosis should be achieved. Anesthesia may be local or general. The usual injections preliminary to local anesthesia are carried out. A curved conjunctival flap, 10 mm. in length, is formed extending from the 6- to 12-o'clock positions (fig. 1). After ex-

The operative area is thus exposed, while the outer portions of the lids and the outer canthus are covered by the conjunctival flap whose raw surface is pointing upward, thereby rendering the area and its surroundings aseptic. The globe is fixed at the insertion of the lateral rectus with a fine-toothed forceps. The scleral incision is made with a sharp keratome in the lower outer quadrant, 8 mm. posterior to the corneoscleral border and oblique to the surface of the sclera (fig. 2).

After the initial incision is made, it is sometimes more convenient to grasp the scleral wound lip itself. The incision is carried through the sclera by successive

light strokes of the keratome and is slowly deepened until the lack of resistance indicates that the sclera has been perforated, due care being taken not to incise the underlying choroid. At this point, an iris spatula, 3 mm. in width, is introduced into the incision in order to test its patency and to determine if it is of sufficient length to facilitate later air injection (fig. 3). The incision can be made longer.

A second incision is now made in the upper outer quadrant in the same man-

globe is fixed by the assistant throughout the performance of the cyclodialysis and other maneuvers involving air or saline injections.

Before beginning the cyclodialysis, the surgeon makes certain that four 5-cc. Luer syringes, with No. 23 B-D. gold cannulas attached, are filled with air which has been sterilized by pulling it through a flame or through cotton wool, and are in readiness. I have found that one accomplishes air injection under pressure more easily and more consist-

Fig. 2 (Barkan). The scleral incision is made with a sharp keratome in the lower outer quadrant, 8 mm. posterior to the corneoscleral border and oblique to the surface of the sclera.

ner. However, care must be taken to make this incision more obliquely than in the lower quadrant, because the sclera is often found to be thinner in the upper than it is in the lower quadrant. This is especially true in primary wide-angle glaucoma, in many cases of which a darkish hue found in the upper quadrant is caused by the uvea shimmering through the sclera which may be of almost paperlike thinness, even though the pressure is not markedly elevated. This incision is likewise tested for its length, another 3-mm.-wide spatula being used.

An assistant now firmly grasps the globe at the contralateral limbus with an Elschnig or Gifford lock forceps. The

ently with a 5-cc. syringe than with a smaller syringe. A syringe is now held by the instrument nurse or by the assistant with his free hand, two inches from the surgeon's hand, in such a position that during the performance of cyclodialysis the direction of the cannula corresponds to the meridian of the globe into which it is to be inserted—the same meridian in which the spatula was inserted. The surgeon now fixes the globe at the insertion of the external rectus tendon while he performs a cyclodialysis with a spatula, 2-mm. wide, that has been appropriately bent. One to 2 mm. of the blade of the spatula appears within the anterior chamber. The handle is rotated in

Fig. 3 (Barkan). An iris spatula, 3 mm. in width, is introduced into the incision in order to test its patency and to determine whether it is of sufficient length to facilitate later air injection.

such a manner that the tip of the spatula moves vertically to just short of the horizontal meridian. It is well to undermine for 3 mm. posteriorly to the corneoscleral border at either end of the sweep and to avoid crossing the horizontal meridian where major blood vessels are located. This maneuver should be followed without loss of a moment by the air injection which has been made ready.

At the moment the surgeon removes the spatula, the syringe with gold cannula held in proper position is placed in his two hands without his having to look up. He inserts it into the incision from which he has just removed the spatula and immediately injects the air into the anterior chamber (fig. 4). This maneuver should

take only a fraction of a second. The quantity of air to be injected in each individual case and whether the air should be under pressure or not are matters of experience and judgment. The chamber is thus restored with air. After waiting a few minutes to allow hemostatic action to take place, a second cyclodialysis is undertaken in a similar manner.

The air lost during performance of the second cyclodialysis is replaced with another injection of air that again restores the chamber and stops hemorrhage. Since, due to the presence of air, the angle has now become image forming, the surgeon may inspect the region of the cyclodialysis by looking across the chamber from the opposite side. If the

cleft is judged inadequate, the cyclodialysis may be enlarged with another spatula, and the air injection repeated.

After a few minutes, when danger of hemorrhage is past, a part of the air may be allowed to escape through a corneal puncture. In order to obtain valve closure this puncture is placed obliquely with a Graefe knife, 1 mm. axially to the corneoscleral border. If preferred, the air may be replaced by physiologic saline solution* injected with a No.-30 needle. This puncture is made sufficiently oblique to assure a valve or trap-door closure. The point of the knife should barely perforate Descemet's membrane, as observed under a binocular loupe. A small air bubble (4 to 5 mm. in diameter) is allowed to remain. When combined with appropriate positioning of the head, it

ating small amounts as indicated. After closure of the conjunctival wound, this

process is controlled by testing with a tonometer, the base of which has been

Fig. 4 (Barkan). Following removal of the spatula, the cannula is inserted into the incision, and air is injected into the anterior chamber. This maneuver should take only a fraction of a second.

will keep the cleft free from blood and help to keep the surfaces apart (fig. 5).

Successful insufflation of the anterior chamber with air is assured by continuing to inject air during removal of the cannula. If the injection of air is stopped prior to removal of the cannula, air will escape during the removal.

The entire chamber may be filled with air, the pressure being adjusted by the amount injected or by secondarily evacu-

sterilized with alcohol and which is held in a sterile clamp, or by testing the dimpling of the cornea with a glass rod.

During the first few days of postoperative care, the patient's head should be kept rotated to the opposite side and raised so that the air bubble will take its position in the chamber angle at the location of the upper cleft. If the patient lies on his unoperated side and is as flat as is compatible with comfort, any slight hemorrhage will gravitate to the lower nasal side away from both clefts. If only

* Because it is to be injected into the anterior chamber, solution from ampules is used.

a single cyclodialysis has been made in the upper outer quadrant, the patient may assume a semisitting position with the head rotated to the opposite side. How effective the presence of air is in widening the cleft and keeping it apart is, as yet, an open question which only further observations can decide. In some cases, the air bubble has appeared to maintain the separation during the first few days of healing.

POSTOPERATIVE PROPHYLAXIS

During the convalescence, maximal miosis should be maintained in order to pull the root of the iris from its base and keep the cleft open. For this purpose, 5-percent prostigmin is instilled, and it may be necessary in some cases to use it as frequently as every three hours and to support its action by the use of a 1-percent eserine ointment. Since there is a marked tendency to formation of pigment adhesions in the pupillary area following cyclodialysis, one drop of adrenalin (1:100) should be instilled, combined with one drop of euphthalmine (2 percent) when deemed necessary during the first several days of postoperative care to prevent the formation of pupillary adhesions of the pigment layer of the iris while the pupil is in miosis. When this is done, the eye must be kept under strict observation and the dilatation of the pupil be only temporary.

As soon as a moderate dilatation of 3 to 4 mm. has been accomplished, the pupil should immediately be contracted again, lest mydriasis encourage closure of the cleft by approximating the root of the iris to its base. This is especially true if it has been necessary to operate with cyclodialysis on a case of glaucoma of the narrow-angle type, or if, in a case of the wide-angle type, the angle is fortuitously narrow.

That the maintenance of miosis is an

effective factor in keeping the cleft from closing was suggested by my experience in several cases of cyclodialysis in which a rapid and sudden rise in pressure occurred several months or years after operation. In the case of an aphakic eye with a very extensive cleft, this occurred after normal pressure had been maintained for eight years without miotics. Since pressure dropped suddenly following contraction of the pupil with miotics and subsequent gonioscopic examination revealed an open cleft, the increased pressure in this case was evidently due to closure of the cleft. I have, therefore, come to the conclusion, which I have carried out in practice, that all successfully dialyzed eyes, even though the cleft be gonioscopically wide and extensive, should continue to be given miotics prophylactically once or twice a day—*not with the purpose of reducing pressure but in order to keep the cleft open.*

There are disadvantages associated with the operation of cyclodialysis. Among these are the secondary hemorrhages that occur during convalescence. In only one case, however, have they interfered with the result. Another disadvantage is the formation of pigment synechiae. This can be prevented in most cases by following the treatment outlined earlier in this paper. There has been no case of iritis or sympathetic ophthalmia.

Formation of cataract or hastening of the development of incipient cataractous changes appears to be the main disadvantage of the operation. This is especially true in those cases in which pressure is reduced to a low normal or below the usual normal limits. Of 70 cases of primary glaucoma, 15 developed cataracts. Ten of these cataracts have been extracted, all with good results. Cataractous changes already present before operation in 16 other cases have increased.

As Reese¹¹ states "eyes with primary glaucoma are more predisposed to the

development of cataract than nonglaucomatous eyes. One third or more of the eyes with primary glaucoma have incipient cataractous changes. Operations for glaucoma in general, and especially the trephine operation, tend to hasten the development of these incipient cataractous changes." Although this statement also applies to cyclodialysis, it should not interfere with the decision to perform this operation in cases of primary, narrow-angle glaucoma with peripheral adhesions, in aphakia, or in subluxation of the lens. In all of these conditions, cyclodialysis possesses marked advantages over other operations for glaucoma.

SUMMARY AND CONCLUSIONS

1. The procedure for cyclodialysis—multiple or single—combined with air injection is described.

2. Air injection controls hemorrhage, widens the cyclodialysis cleft, makes the cleft visible, and, by restoring and deepening the anterior chamber, makes possible a multiple cyclodialysis.

3. Multiple cyclodialysis with air injection is safer and more effective than a large single cyclodialysis performed according to the usual method. By employing multiple cyclodialysis, it is possible to make a permanent dialysis more consistently, with less trauma and without hemorrhage, and to promote, under visual control, the formation of a permanent cleft of sufficient size.

4. Under certain conditions, continuance of air pressure in the anterior chamber produces obstruction, retention, and thus artificial glaucoma.

5. Cyclodialysis combined with air injection is indicated in primary glaucoma of the wide-angle type. It is especially indicated, to the exclusion of trephination, iridencleisis, and iridectomy, in the late stage of the narrow-angle type after peripheral adhesions have closed the angle

in large part, irrespective of whether there is congestion or not. It is indicated in those varieties of secondary glaucoma for which cyclodialysis is the commonly accepted operation.

6. The operative procedure consists of the following steps:

- a. Preoperatively, extreme miosis should be achieved.
- b. Following the cyclodialysis, air is injected.
- c. The second cyclodialysis is made through a scleral incision in the adjoining quadrant.
- d. Following the second cyclodialysis, air is again injected. The cleft is examined by visual control and, if deemed necessary, it can be enlarged and the air injection repeated.
- e. Hemorrhage having been prevented, air is replaced after a few minutes by physiologic saline solution, if it is desired.
- f. A small air bubble is left in the chamber to promote separation of the cleft and to keep it free from blood.
- g. Prostigmin (5 percent) is instilled postoperatively to maintain maximal miosis. Postoperative maintenance of miosis is an effective factor in keeping the cleft and the channel of outlet from closing.
- h. Adrenalin (1:100) and euphthalmine (2 percent) should be instilled at intervals of a few days to prevent formation of pupillary adhesions. Mydriasis must be transient only, and must be adequately counteracted by miotics.

7. A miotic should be used once or twice daily permanently as a prophylactic to assure maintenance of the cleft and channel.

OPHTHALMOLOGY DURING THE WAR AND IN THE FUTURE*

SIR STEWART DUKE-ELDER

London, England

It is indeed with the greatest diffidence that I am presenting you with this paper. I am profoundly aware of the honor which your Society has done me at this time, and I feel, as is perhaps natural, that the least I should be able to do in reply is to attempt to return the compliment by making this the occasion of a great effort on my part to present something really new and striking to you.

Such, alas, is not to be; for new conceptions do not come lightly but only after much work and thought, and the years which have just passed have been years of destruction rather than of construction. For six of them I have been away from my clinics and my laboratories, and, apart from enrichment from

many types of experience—not the least of which was meeting large numbers of friends and colleagues from this side of the Atlantic in many parts of the world—on the whole, the content of these years must be added to the mountain of waste which seems always to be characteristic of war. And so I have come to you empty-handed, with little more than apologies. But, knowing you, I have little fear that these apologies will readily be accepted.

Having nothing new to offer you, I hope you will not think it out of place if I spend a little time considering what ophthalmology has done in the war in the clinical sense—not in the technical sense—and what we may hope it will do in the immediate years to come.

Looking back, it seems to me extraordinary how few are the surgical advances that have arisen directly out of the war. One always associates the ex-

* Read at the 82nd annual meeting of the American Ophthalmological Society at San Francisco, California, June, 1946.

periences of war with its mass mutilation and its herding together of great numbers of people in artificial circumstances and its consequent opportunities for large-scale coördinated investigations and controlled experiment, with considerable advances in the science of medicine and the technique of surgery.

The advances in general surgery in the first World War were great. In ophthalmology during these years, to quote two instances, our technique in dealing with intraocular foreign bodies was revolutionized and our conceptions of the minute central localization of the visual functions were for the first time put on a secure observational basis.

In this war, fundamental progress in surgery has been less striking. It is true that there have been innovations in surgical technique, but most of them have been incidental and detailed, and even the holocaust of intraocular foreign bodies with which we were inundated in the field and at home through bombing has left the position relatively unchanged. It is also true that new ideas such as the ingenious Berman locator have been elaborated, and that methods, some of them more ingenious than safe, have been suggested for the extraction of nonmagnetizable foreign bodies.

Novel and probably fruitful suggestions have also been made in the fitting of artificial eyes. But in the main these, and other surgical innovations, are incidental refinements of already accepted principles. There has been nothing completely new of first-class importance and revolutionary scope such as the introduction in the previous decade of operations for the reposition of retinal detachments or the popularization of the technique of corneal grafting.

ADVANCES IN CHEMOTHERAPY

In ophthalmic medicine the greatest

advance has, of course, been made in chemotherapy. The original sulfonamides introduced before the war have benefited by mass application and intensive study, and their place in ophthalmology—a very useful one—has now become firmly established. Newer compounds, improving on the old by increased effectivity and decreased toxicity, have followed each other in rapid succession. Furthermore, the magic of penicillin, locked up in obscurity in a laboratory in London for more than a decade, has been exploited and has produced revolutionary results quite unequalled in its field in ophthalmic history. It must be admitted that neither of these advances was primarily ophthalmological; but we can claim that ophthalmology has not been behindhand in their exploitation.

It is probably the case that most ocular inflammations are not infective but rather allergic or reactive, corresponding in a sense to the so-called rheumatic inflammations of synovial membranes, and, therefore, the bacteriostatic drugs are less applicable to our specialty than many other parts of the body. But the advances of the last 10 years whereby many organismal intraocular infections can be aborted or controlled by the sulfa drugs, and more extraocular infections can be still more dramatically overwhelmed by penicillin—when, for example, gonococcal conjunctivitis can be cured in fewer hours than it took weeks in a previous generation—are indeed remarkable.

It is true that Florey would have abstracted penicillin from Fleming's laboratory if there had been no war; but without the war to stir our two governments from their customary lethargy toward medical progress to throw all their resources into the fullest and most rapid exploitation of these drugs, we would, I am sure, be much further behind than we are today in our therapeutics.

PHYSIOLOGY OF VISION

PRACTICAL APPLICATIONS

As a direct result of the war most work—at any rate in my personal experience—has concerned itself with the practical applications of the physiology of vision. Most of the work on which large numbers of people in both our countries were employed was very specialized and much of it has not been published. At any rate, my knowledge of the optics of gunsights, range-finders, periscopes in tanks, graticules in telescopes, viewing and scanning devices, the lighting of instrument panels, dials and controls, the uses of goggles, problems of dazzle, scatter and haze, and, above all, of night vision and dark adaptation has increased beyond all bounds. But most of this has been the meticulous application of the detail of principles already known to a type of practice which demanded the utmost refinement of exactitude.

Two real advances have been made—or rather have been begun—both of which may yield results of great practical and constructive value: the study of the performance of the eye at high altitudes, and the study of the scotopic or rod fields. It is an extraordinary thing that all the work done upon the visual fields—and it has been great in volume and in achievement—has been upon the daylight field of the photopic eye. Only recently, so far as I know, since it was started by Livingston in London, has the rod field of the dark-adapted eye been investigated with some of its vagaries in pathologic states. Although the technique is laborious and time-consuming, the further exploitation of this may lead to results in clinical ophthalmology of more than usual interest.

FUNDAMENTAL ASPECTS

On the more fundamental aspects of

the physiology of vision, however, I think we are on the threshold of a big and exciting revolution in thought—despite, and not because of, the war.

On the photochemistry of vision and the role of visual purple and its relationship to vitamin A, our knowledge is becoming much more precise. In this connection the outstanding work of Selig Hecht in New York and George Wall at Harvard must receive very special mention. Our knowledge of the photochemistry of the cones is just beginning.

What is more intriguing, studies in dark adaptation—particularly those conducted in London by Lythgoe whose early death is a great tragedy for this branch of our subject—are beginning to show that the mechanism of adaptation is not entirely chemical, but that a nervous mechanism comes into play as well. Possibly there is a rearrangement of the inter-retinal synapses by which there develops a decreasing ability to perform the finer visual judgements and at the same time an increasing ability to initiate a cruder impulse on minimal stimulation.

This brings us at once to the monumental histologic research of Polyak in Chicago on the inter-retinal association and integrating systems. It is curious that since the early work on the intimate anatomy of the retina conducted about the middle of the last century by such investigators as Müller, Schultze, and Schwalbe which culminated about the end of the century in the classical researches of Ramon y Cajal, little or no investigation has been undertaken, and it is difficult to realize that the numerous schematic diagrams of the intimate morphology of this tissue that appear so established in our textbooks, all of them copied from Cajal's work, are based more upon speculation than upon established neurohistologic fact.

Our classical conception of the struc-

ture of the retina is insufficient to explain many phenomena of vision related to visual acuity, color vision, sensory gradients, the interrelation of retinal areas, and so on. Histology has remained very far behind the advances in the physiology of vision. Some of Polyak's theoretical deductions from his studies may be open to question, but there can be no doubt that the possibilities of an anatomic groundwork for integration and association, as well as of inhibition in the photoreceptive apparatus, are full of promise and must be explored further.

ELECTROPHYSIOLOGY

In the meantime further—and, to my mind, still more fascinating—evidence has come from another quarter—electrophysiology with the use of the microelectrode technique whereby the impulses of single nerve fibers are picked up and analyzed, work commenced by Adrian in Cambridge and continued by Granit in Stockholm.

This microelectrode technique which picks up and amplifies changes in potential of a single fiber in the optic nerve when a cone or rod is stimulated by light is a beautiful procedure, demanding great skill and aptitude on the part of the experimenter. It has brought to light results of exceptional interest.

When the response-curves are assorted into groups, eight separate types are found in most animals. The first type, which has a broad response-curve, is stimulated by nearly all parts of the spectrum. This Granit calls a "dominator." The remaining seven types, all of which have a narrow response, are stimulated by one part of the spectrum only. These Granit calls "modulators."

This discovery does not seem very hopeful for the survival of the trichromatic theory of vision; a polychromatic theory would appear to be indicated. The results so far have been obtained only on experimental animals, but it is prob-

able that similar results would be obtained on man, a question the testing of which is now being investigated.

Other physiologic observations recently made are disturbing for the old hypothesis of Thomas Young, according to which certain cones respond to red, others to green, and others to blue light—the establishment by Shlear in America and Hartridge in London, for example, that the acuity of the eye in colored light was identical with that in white of equal intensity. Equally interesting is the demonstration that the spurious colors of the chromatic aberration of the eye are not neutralized physically but are eliminated by a nervous response.

There is little doubt, I think, that with the elaboration of microtechniques applied to the visual system and the facilities offered by the new electrophysics which gave us radar, great advances are due in our knowledge of the mechanism of photoreception whereby it is possible that many of our old ideas, accepted so long that their status as hypotheses has almost been forgotten, will require drastic revision.

When the same process is carried further into the central nervous system after the manner of Talbot and his co-workers in Baltimore, there is no knowing where we shall end. The next 10 years promise plenty of excitement, and I would like nothing better than to pass them with a microelectrode.

VEGETATIVE PHYSIOLOGY

Let us turn to what I like to call the vegetative physiology of the eye. Here I think developments no less exciting are impending. Let us look at the most fundamental problem in this branch of our subject—the formation and the elimination of the intraocular fluid and the control of the ocular tension.

When at the end of the last century Leber brought forward his theory of the transudation of the intraocular fluid from

the ciliary capillaries and its drainage through the canal of Schlemm, it seemed for a long time as if the last word had been said upon the subject.

The advances of physicochemistry in the first quarter of this century revealed that this hypothesis was inadequate, and in the later twenties I elaborated the theory that the aqueous was a dialysate of the blood in physicochemical equilibrium with it and that superimposed on this dialysation was a secondary circulation determined by pressure differences.

Now, in the forties, history is repeating itself. While to the relatively crude experimental methods which were at my disposal 20 years ago the postulates of dialysation seemed fully satisfied, the finer and more accurate methods of today have shown them to be insufficient. During the last 12 years, Jonas Friedenwald in Baltimore, in a prolonged series of brilliant and sustained researches (whose value I appreciate most highly), has been attacking the hypothesis of dialysation. From Philadelphia Francis Adler, in a quieter way, has been doing much the same thing. And, just recently, typically without any warning, David Cogan and Kinsey have thrown an atom bomb into the arena, and, using heavy water and radioactive elements from the cyclotron at Harvard, have shown that we all will need to start to think again.

Twenty years ago, in the arrogance of youth, I thought I had found the last word. Today, as I grow old, I also grow modest. But still I think I am fundamentally correct in the view that the aqueous is essentially a dialysate, although its constitution is almost certainly modified by the interposition of a membrane or membranes, of which we know little, between the blood and the chambers of the eye, and certainly is modified by metabolic processes within the eye.

Lest Friedenwald may think that some of the excitements of battle have gone out of his life, I would suggest that some

of his work may bear alternative explanations. I do not think his demonstration of the unidirectional permeability of the ciliary epithelium to water is wholly convincing; I do not agree that the irreciprocal permeability of the ciliary epithelium to acid and basic dyes—which he has demonstrated most beautifully—implies a similar permeability to all ions: in fact, just before the war, I satisfied myself that it was not so.

If the penetration of dyes is to be relied upon as an index of a secretory activity, then we must endow, for example, the membrane of the red blood cell with secretory activity. Friedenwald's demonstration of an oxidation-reduction system based on vitamin C in the ciliary stroma is a beautiful piece of work, and his finding that diminution of the vitamin impairs the formation of the plasmaoid aqueous formed after paracentesis would suggest that it has considerable significance; but what that significance is I do not know.

It is conceivable, for example, that it may be associated with the capillary endothelium, in the vitality of which there is some evidence that the oxidative vitamins of the B group are intimately concerned. At any rate in the next 10 years it is to be a great adventure to try to find out. My next 10 years, you will observe, are to be fully occupied; for the spare time left over from the microelectrode should be spent spiritually between the Wilmer Institute and the cyclotron at Harvard.

PHYSIOLOGY OF THE CORNEA

About the vitreous there is little fundamentally new, but, with the electron microscope and radioactive tracer elements at our disposal, there is the prospect of further advances in our knowledge of its structure and metabolism.

To a considerable extent the cornea has come to life again. Leber in 1873 advanced his theories on the lymph cir-

culution in this tissue, and there our knowledge remained substantially until the studies of Fischer in 1928 elucidated its respiratory mechanism. Recently Cogan and Kinsey have taken up the subject and have suggested in a very conclusive way a new mechanism for the fluid-traffic of this tissue.

This opens up a new approach to the physiology of the cornea, about which we know so little. Even about its autoxidation mechanisms we know nothing. It always strikes me as peculiar that we know so little about the pathology of the cornea for it is a transparent tissue, exceedingly accessible and relatively isolated. It was used by the early pathologists in the middle of the last century to appreciate the general changes characteristic of inflammation, and since their relatively crude observations little more has been added.

It has always been a disappointment to me that the great amount of time that so many of us have expended on the study of the action of the war gases on this tissue was so dominated by the immediate emergency and led to no more fruitful results. It seems not without the bounds of possibility, however, to suggest that, with all the refinements of technique available today, the intensive and intimate study of this tissue in disease might not only add to our local knowledge but also provide the groundwork for further advances in the fundamentals of the pathology of inflammation generally.

PHYSIOLOGY OF THE LENS

So, too, with the lens. Our knowledge of this tissue, particularly of its respiratory mechanism and the essential part played therein by the vitamins of the B and C groups, is increasing rapidly—work of great interest wherewith the name of Bellows of Chicago is closely associated.

Here again we have a system unique in the body, readily seen, easily manipulated, and perfectly isolated for experimental purposes whose continued health seems dependent essentially on the integrity of its intracellular oxidative systems. I do not think it is too much to expect that in the next 10 years, given sufficient enthusiasm, not only may some of the problems of cataract disappear but valuable pointers may be provided for the understanding of the general problems of sclerosis and senility wherein an oxidative failure of the same type is probably a crucial factor.

EVALUATION OF EXPERIMENTAL OPPORTUNITIES

COMPLETE REVOLUTION IN METHODS

It would seem that the program for the next 10 years is very heavily booked up. I may speak hopefully, but I do not think I am expecting too much. For now we have available to us a complete revolution in methods.

I am not suggesting that the classical modes of inquiry by clinical examination and cellular pathology are outmoded or have yielded their full harvest, but there seems little prospect of further revolutionary advances with their aid.

Recently it has become possible to change our method of inquiry. Instead of busying ourselves with the structural ruins which disease has left behind it, as is the province of pathology, we are now able to probe more deeply and examine the more subtle nature of the initial defect, to pass from the study of structures composed of cells to the study of cells composed of molecules and atoms.

Now, equipped with techniques whereby micro-analyses of a minute drop can be undertaken more accurately than the gross analyses of a generation ago, whereby it is easy to estimate the pH of a single cell or pick up and analyze the

action current in a single nerve fiber excited by a single band of wave lengths, when we look not with microscopic or even ultramicroscopic eyes but with electron microscopes whereby viruses can be seen rather than believed and a single cell is too gross an object for adequate study, when we can follow metabolic processes with labeled elements throughout all the intricacies of metabolism—with all this equipment opening up all these new worlds, we should make great strides.

Some months ago I read in one of our more inaccurate newspapers—we have this kind of newspaper in my country as well as yours—that the discovery of carbon 13 would shortly revolutionize medicine and yield up the secret of life itself. The reporter did not know that at the time he wrote carbon 13 was already old-fashioned; but the fact remains that this may be an overstatement and it may well not. But, whether it is or not, no one can complain of the variety and scope of the opportunities that are offering themselves, or of the difficulty, the complexity, and the interest of the problems facing us.

There is another very important matter. The older methods were observational only: the newer ones can make fuller use of the experimental method. They can take nature and, so to say, put her in the witness box, and, taking purposely one variable at a time, analyze her secrets much more thoroughly. It is entirely owing to the exploitation of the experimental method that medical knowledge has bounded forward in the last half century out of all comparison with its previous progress; and nowadays we can get down to the experimental method in real earnest.

SCIENCE OF OPHTHALMOLOGY

It may be said that the advances of which I speak are physiological rather

than clinical. But advances in the practice of medicine can only go as far as the fundamental sciences on which they are based have advanced. That, I think, is the most hopeful aspect of the matter, for it may be that we are at last approaching a stage where a *science* of ophthalmology may begin to emerge. By that I mean an organized system of knowledge dealing with first principles upon which a study of disease of the eye can be philosophically based.

What, for example, are the common denominators whereby a cell in the cornea, the lens, or the retina changes its reaction, loses its bipolarity, and dies? Suppose, to look at it the other way, I take one fundamental process, a failure in intracellular oxidation—caused, of course, by many factors—how many of the hundred diseases of the cornea would that embrace in a single rational generalization—as well, perhaps, as the whole of the pathology of the lens?

The defect of ophthalmology at its present stage of development is that it is too compartmentalized, lacking an ordered sequential philosophy of cause and effect.

Observational ability is indeed plentiful, but the wisdom required to assess the mass of observations is at a much higher premium.

Can I illustrate this in two ways? In the first place, in our clinical thinking and in our textbooks, we tend to visualize diseases as if they were specific entities like butterflies or flowers to be labeled or classified in a museum. In like manner we demonstrate to our students an unending series of disease-pictures which they are supposed by a prodigious feat of memory to collect and store, each in a separate compartment, before they go out into the world.

If medicine did not progress, there might be some practical reason in this. But as medicine advances the disease-

pictures alter, new descriptions of associated symptoms appear, and new conceptions call for a new nomenclature; and furnished only with dogmatic teaching and untaught to reason and synthesize from first principles, because the first principles are as yet not clear, he is often lost if the groove in which his mind has been trained changes its shape.

Each new disease, however, that appears in the literature is not a new morbid entity discovered as Columbus discovered America. It is merely the recognition of a reshuffling of the basic reactions of the tissue cells; and, although the disease-pictures are artificial and ephemeral, if we go deeply enough, the underlying basic reactions to disease are perpetual and always remain unchanged.

INTEGRATION OF RESEARCH

So, too, with research: it is yet in large measure the making of a mass of observations, most of them disparate, with too little of the philosophy of synthesis and integration. For too long we have been forced to accumulate masses of apparently unrelated facts which swell beyond all reason a vast literature. As yet, they await adequate interpretation and integration into a body of coherent thought.

As the pile of information gets higher we require more and more time to acquaint ourselves of it and have less and less time to think about it. Like George Bernard Shaw we shall require to go back to Methuselah and live for 400 years if we are to be really wise, unless someone can find the common denominators, the basic generalizations by which our vast knowledge can be synthesized into a coherent scheme.

This stage may not be so very far away. And even if our first schemes are temporary—partly or even largely wrong—they will certainly serve a useful purpose if they merely act as a scaffolding for further constructive building.

RESPONSIBILITIES OF THE FUTURE

I would like to close with a remark on our responsibilities at the present time. I have seen most of the European countries since the war ended, excluding those, of course, in the East which are guarded with such secrecy by our allies. They all show the same physical picture of destruction and abolition of facilities, the same mental condition of fatigue and apathy. Out of Europe and particularly out of Germany a great amount of research and original thought used to emanate year by year by which our science was constantly enriched.

For a generation at least, and probably for two, this rich reservoir will be dried up. Research is not an easy thing to start, and, apart from individual brilliant exceptions, the student requires to be inspired by teachers who themselves have grown up in the stimulating atmosphere and philosophic background of research.

I do not think that European culture is dead: it is too traditional and fundamental in European thought and life to be killed so easily. But it is very tired: and, if I am right in thinking that as a result of the catastrophic break in the continuity of original scientific thought in a collapsed Europe, a whole generation will need to live and die before a full renaissance of research can be expected, it follows that the duty and responsibility of maintaining progress, of keeping alive the traditions of research and handing them back again to a recovered Europe devolves upon the English-speaking world, for there is no other competent. That means, at the moment, at any rate, that the survival and the revival of ophthalmology—the realization of all these intriguing potentialities—depend upon the United States of America, with its greater size, its larger facilities, and its escape from material destruction, that is, essentially upon you in this Society.

63 Harley Street (W. 1).

NEW YORK AS AN OPHTHALMOLOGICAL CENTER*

BERNARD SAMUELS, M.D.

New York

It is an old story, often repeated, how in the year 1816, Edward Delafield and John Kearny Rodgers, while attending lectures at the London Eye Infirmary, now the Royal London Ophthalmic Hospital, resolved, with youthful aspiration, to found a similar charity in their native New York—"for the first time in Ameri-

official title of New York Eye Infirmary, received a charter from the legislature, for the purpose, in quaint and sweeping terms, of "curing indigent persons affected with blindness and other diseases of the eyes and ears." From the seed thus sown sprang the New York Eye and Ear Infirmary (fig. 1) and indirectly all kin-

Fig. 1 (Samuels). Present buildings of the New York Eye and Ear Infirmary at Second Avenue and 13th Street.

ca," as they declared. In fulfillment of this resolve, they opened the New York Eye Infirmary on August 14, 1820. The first recorded patient to come on that day to the first eye clinic in New York was one suffering from a fistula of the lacrimal sac. It is of interest that this individual disappeared before the treatment was concluded, thus becoming the first of an ever-lengthening line of runaway eye patients!

In March, 1822, this month a century and a quarter ago, the charity, under the

dred institutions now existing in this city.

Any account of the rise and progress of ophthalmology in New York during the early years must be told in terms of this Infirmary, for around it revolved all matters that concerned the eye and its diseases.

Ophthalmology was the first branch of medicine in New York to be accorded recognition as a distinct specialty by the profession and by the lawmakers of the state.

The early staff of the Infirmary were general practitioners connected with the New York Hospital (fig. 2) who sought to learn to treat disease of the eye, and

* Read before the Section of Ophthalmology of the New York Academy of Medicine at the celebration of the Centenary of the Academy, on March 17, 1947.

Fig. 2 (Samuels). An early view of New York Hospital.

Fig. 3 (Samuels). The first home of the New York Eye and Ear Infirmary.

to teach others to do so, as skillfully as they believed they were treating disease of other organs. They argued that in no better way could these purposes be attained than in an infirmary to which those suffering from disease of the eye could be referred and there lodged and nursed. The idea of a physician's devoting his practice solely to the eye was far from their thoughts.

During the first 30 years of the life of the Infirmary, little advance was made in the practice of ophthalmology. The methods that the founders had introduced from London were continued. Focal illumination and the magnifying glass had not come into general use. Trachoma, which was prevalent, was treated, year in and year out, with touchings of silver nitrate and the copper stick. Atropine was the only mydriatic known, and it was not realized that its use might cause glaucoma. Miotics were unknown. The tension, taken with the fingers, was recorded as natural or hard or soft. To prescribe glasses was considered beneath the dignity of a physician. People "selected" their glasses, even after cataract extraction, from opticians as had been done for centuries.

The Infirmary, after occupying one remodeled building after another, in 1856, settled down at its present site in a structure specially built for its use (fig. 3). Here it has stayed for 91 years, a longer period in one place than has any other hospital in New York except Bellevue. The dedication of the Hospital came at an opportune time, in the middle of the most fruitful and brilliant decade in the history of ophthalmology. In 1851, Helmholtz produced the ophthalmoscope which revolutionized the diagnosis and treatment of disease of the eyes. A brief four years later Jaeger, in Vienna, published an *Atlas of Diseases of the Fundus*, drawn and colored so true to nature as to

be unexcelled. In 1856, Donders published his work on the *Anomalies of Accommodation and Refraction*. In 1857, Graefe gave to the world the operation

Fig. 4 (Samuels). Cornelius R. Agnew.

of iridectomy for the treatment of glaucoma.

In no other city was the effect of the knowledge that was unfolding in Europe more potently felt than in New York. Just prior to the Civil War, Cornelius R. Agnew (fig. 4) and Henry D. Noyes (fig. 5) returned to the Infirmary after completing their medical training abroad as was the practice of the times. They had studied under Graefe, Donders, and Bowman, known as the triumvirate of ophthalmology. Provided with the facilities of a new hospital, they instructed their less-traveled colleagues in the use of the ophthalmoscope, a cumbersome instrument difficult to master. The first evidence of experience with the new instrument is shown in the *Annual Report of the Infirmary for 1860*, in which appear such terms

and Ear Hospital.

Fig. 7 (Samuels). The
Manhattan Eye, Ear, and
Throat Hospital.

as choroiditis, tumor of the choroid, apoplexy, and detachment of the retina. The following year optic-nerve atrophy was added to the list. Not long after astigmatism was recorded, which implies that the surgeons were reading Donders!

In 1864, in recognition of the fact that disease of the ear had always been treated at the Eye Infirmary, the title was legally changed to the New York Eye and Ear Infirmary.

The occasion permits of scarcely more than mention, in chronological order, of eight institutions of similar kind that have come into existence since the Infirmary was founded. Probably no city can boast of having had so many.

THE NEW YORK OPHTHALMIC HOSPITAL

The New York Ophthalmic Hospital was founded in 1852, chiefly to afford facilities for the instruction of medical students in the treatment of diseases of the eye. At first the allopaths had charge of the treatment but, as the Hospital did not prosper under this system, it was placed in the hands of the homeopaths who continue its long and praiseworthy career in association with Flower-Fifth Avenue Hospital and New York Medical College.

THE BROOKLYN EYE AND EAR HOSPITAL

The Brooklyn Eye and Ear Hospital (fig. 6) was founded in 1868 under the leadership of Agnew. Its birthplace was a remodeled dwelling house. No sooner had it settled down than it was dispossessed to make room for the east approach to the Brooklyn Bridge while the west approach overshadowed the birthplace of the old Infirmary. It now carries on its enormous work in a building which for equipment, size, and beauty is the pride of the profession.

THE MANHATTAN EYE, EAR, AND THROAT HOSPITAL

The Manhattan Eye, Ear, and Throat Hospital (fig. 7) was opened in 1869, in a remodeled residence, also under the auspices of Agnew. At first it was empowered by charter to treat only diseases

Fig. 5 (Samuels). Henry D. Noyes.

of the eye and ear, as its name then implied. Later a nose and throat department was instituted and still later a department of nervous diseases was added. It is authorized to conduct a school for the teaching of these subjects. The Manhattan is famous not only for the wealth of its clinical material but also for the variety of activities carried out under its roof. Here the idea for the Eye Bank to ensure material for corneal transplantation originated. Here is conducted a clinic devoted exclusively to the treatment of glaucoma, sponsored by the National Society for the Prevention of Blindness.

Fig. 8 (Samuels). Herman Knapp Memorial Eye Hospital.

THE HERMAN KNAPP MEMORIAL EYE HOSPITAL

In the minutes of a meeting of the Academy, in 1868, there is an entry that Herman Knapp, late Professor of Ophthalmology of Heidelberg, was introduced. Although insignificant in itself, this scene marked the beginning of a career that was to exert a profound influence. A year later, under charter by the state, Knapp opened the Ophthalmic and Aural Institute in two private residences. It was conducted after the pattern of Graefe's famous eye clinic in Berlin, where the poor crowded into the lower stories while the rich thronged into the upper ones. Eye hospitals in New York had been solely the refuge of the poor. The well-to-do were operated upon

in their own homes. The admission of private patients into the Institute made scandal, which sounds strange today when private, semiprivate, and ward-private patients all but dispossess the indigent. The Institute grew so rapidly that in a brief period only the New York Eye and Ear Infirmary and the Massachusetts Charitable Eye and Ear Infirmary drew more patients. Its independent life spanned 70 "honorable years." More recently, it was known as the Herman Knapp Memorial Eye Hospital (fig. 8). Finally, in 1941, it was merged with the Eye Institute of the Presbyterian Hospital.

THE HARLEM EYE AND EAR INFIRMARY

The Harlem Eye and Ear Infirmary (fig. 9) received corporate powers in 1881. It was the first special hospital located north of 41st Street. It began in a little room back of a plumber's shop, the most lowly birthplace of any. Largely through the efforts of public-spirited residents of the neighborhood, a splendid structure has been provided.

THE NEW AMSTERDAM EYE AND EAR HOSPITAL

The New Amsterdam Eye and Ear Hospital was established in 1888. It was destined not to advance beyond the altered private-residence stage. In 1911 it received permission from the courts to sell its property and "cease to exist"—an example of what happens when a hospital gets too deeply into debt!

THE BRONX EYE AND EAR INFIRMARY

The Bronx Eye and Ear Infirmary (fig. 10) received its license from the State Board of Charities in 1901. It is maintained primarily for the benefit of all persons unable to pay, suffering from disease of the eye, ear, nose, and throat. Its modern building bears witness to its signal success.

Fig. 9 (Samuels). The Harlem Eye and Ear Hospital.

THE INSTITUTE OF OPHTHALMOLOGY

In 1933, the Institute of Ophthalmology (fig. 11) came into being, under the most auspicious circumstances, as a unit of one of the world's largest and richest hospitals. It is the only foundation in the city devoted exclusively to the eye. Facilities for the treatment of ocular disease are combined with opportunities for sci-

entific study. Its success was assured by the appointment of John Martin Wheeler, a gifted surgeon, teacher, and executive, as its first director. Its staff was largely recruited from that of the old Infirmary which has served as a sort of proving ground for almost every similar hospital in Greater New York. The Institute has set an example of a cultural kind by

Fig. 10 (Samuels). The Bronx Eye and Ear Infirmary.

Fig. 11 (Samuels). The Institute of Ophthalmology.

organizing a museum in which instruments, manuscripts, and letters of historical interest form the nucleus of a rare collection. The library contains 5,000 bound volumes and over 5,000 reprints.

THE NEWARK EYE AND EAR INFIRMARY

Although the Newark Eye and Ear Infirmary is in another state, New York claims it as its own. It started in 1880, like others, in a remodeled residence. Faithful to its consecration, no patient has ever been turned away because of inability to pay.

SURGERY

Good surgery is traditional in New York. In the early days, ophthalmic surgery fell within the domain of the general surgeon. John Kearny Rodgers, one of the most distinguished surgeons of New York, as an eye operator, was

described as being "quick, skillfull, and brilliant." Rodgers taught Noyes, who paved the way for Weeks in plastic surgery, and Weeks taught Wheeler and Goldstein. So elegant and dexterous were the three in plastic work that men came from far and wide to witness it. Robert G. Reese and Edgar S. Thomson were noted for the success of their intraocular operations—to watch them was considered to be educational. Jameson's procedure in muscle operations is a standard in surgery. Pressing forward in even greater refinement of technique, the surgeons on active duty are worthy successors. There is value in working in groups; thus, the staff of one hospital may excel in the extraction of cataract, the staff of another in glaucoma operations, and the staff of still another in corneal transplantation. As a matter of course, whoever would keep abreast of ophthalmic

surgery comes to New York and makes the grand rounds.

TEACHING

It has been said that the creation of every hospital means at once the creation of a school. Scarcely had the old Infirmary been started before an entry appears in the minutes that a series of lectures on the eye had been begun by Delafield. In the first years, in order to stimulate

to the schools of Europe. There is being given today by the Medical Department of New York University a postgraduate course on the eye which for organization, scope, and large number of students probably surpasses any previous effort of its kind. The Instruction Hour conducted before each stated meeting of this Section serves good purpose. The Refresher Course, given here and there, is so timed as to come just before the meeting of

Fig. 12 (Samuels). An aerial view of New York Hospital.

the teaching of ophthalmology, the state went so far as to make an annual appropriation, the Infirmary contracting to allow two physicians from each county to witness the practice and surgery. The first systematic course in ophthalmology was that given by the homeopathic New York Ophthalmic Hospital in the 1850s. This is the only hospital authorized by law to confer a degree: *oculi et auris chirurgus* (Surgeon of the eye and ear). The New York Ophthalmic and Aural Institute conducted courses that rivaled those that had hitherto lured Americans

the American Board of Ophthalmology.

Uninterruptedly through decades the New York Postgraduate School and Hospital and the New York Polyclinic Medical School and Hospital have attracted a stream of students from all over the world, adding immensely to the prestige of ophthalmology in this city. The Department of Graduate Medical Instruction of Mount Sinai Hospital, in its ophthalmic division, has cause to be proud of the men it turns out. The New York Hospital, which sheltered the Infirmary from 1824 to 1826 and then withdrew its

help, as if to make amends for lack of vision, now maintains in connection with Cornell University Medical College (fig. 12) an eye department which is in all but name an institute. Who does not recall with gratitude, at the threshold of his career, some assistant surgeon who, while inconspicuously bearing the brunt of the clinic, went out of his way to instruct and hand down the traditions of his specialty?

RESEARCH

In 1887, John E. Weeks (fig. 13) read a paper before this section entitled: "The

Fig. 13 (Samuels). John E. Weeks.

Pathogenic Microbes of Acute Contagious Conjunctivitis, Based on 250 Cases Observed—Popularly Known as Pink Eye." This was the fruit of the clinic and laboratory of the New York Ophthalmic and

Aural Institute. In recognition of the fact that Knapp equipped and supervised the research work in this laboratory, which was the first of its kind in any eye hospital in the United States, it is fitting that an endowment, under the control of Columbia University, should bear the name of the Herman Knapp Memorial Foundation in Ophthalmology. The income derived from the endowment is expended for study, postgraduate teaching, and fellowships.

The Ophthalmological Foundation, Incorporated, has for its chief purposes the organization of research in problems relating to blindness and the compilation and distribution of information on this subject in coöperation with the National Society for the Prevention of Blindness. The Eye Surgery Fund, Incorporated, seeks to provide books, instruments, and models for the instruction of residents. To assist in solving an obscure surgical problem, it may defray the hospital expenses of the patient and provide the means for the publication of the case. The Eno Laboratory of the New York Eye and Ear Infirmary has accumulated thousands of microscopic preparations of the eye which are so classified as to be available for investigations. Not the least service rendered by the endowments is the scientific spirit that they are arousing. Whereas, formerly, research in hospitals was scarcely tolerated, now it is the avowed policy to foster it.

LITERATURE

A vast literature has emanated from the pens of New Yorkers in the form of books, treatises, monographs, atlases, and articles in current journals. To name a few, the textbooks by Noyes and Weeks were comprehensive and widely used in their time. Loring's *Textbook of Ophthalmoscopy*, with the ophthalmoscope that he devised, served to enlighten a whole

generation. Herman Knapp enriched the literature by the importance and number of his contributions. In 1869, he founded the *Archives of Ophthalmology*, in which the Transactions of this Section have always appeared. Török and Grout's *Surgery of the Eye* and Oatman's *Diagnosis of the Fundus Oculi* came out in 1913. The *Collected Papers of John Martin Wheeler*, which reveal the progress of his surgical career from 1909 to 1938, are invaluable. May's *Manual of the Diseases of the Eye*, now in its 17th edition, speaks for itself. *The Eye and Its Diseases*, edited by Berens, is consulted by all. Berliner's *Biomicroscopy of the Eye* is indispensable in the library. Troncoso's *Internal Diseases of the Eye* and *Atlas of Ophthalmoscopy* has been followed in rapid succession by Evans' *Introduction to Clinical Scotometry*, Elwyn's *Diseases of the Retina*, Hughes, *Reconstructive Surgery of the Eyelids*, and Berens and Suckerman's *Diagnostic Examination of the Eye*. Duane's translation of Fuchs's *Diseases of the Eye*, with his own chapter on muscles, aside from its inestimable medical value, is a literary product of the highest order. No such monumental opus as the *System of Diseases of the Eye*, in four quarto volumes, by Norris and Oliver of Philadelphia, has ever been attempted by New Yorkers, but, nevertheless, they have done their full share in the written word.

THE LOCAL SOCIETIES

The New York Ophthalmological Society was organized, in 1864, by men

who had formed warm friendships while pursuing their studies abroad. For many years the members met in one another's homes. To this day a cordial and informal atmosphere pervades its meetings. The Brooklyn Ophthalmological Society is of proud lineage. Its meeting place is the

Fig. 14 (Samuels). The New York Academy of Medicine.

King's County Medical Society Building, which houses a select and extensive collection of eye books. There is still another society, recently organized, the New York Society for Clinical Ophthalmology. Its chief aim is to make its programs valuable and instructive to younger men. Its meetings, preceded by an "instruction hour," are held at the Academy.

THE NEW YORK ACADEMY OF MEDICINE

The observance of the Centenary of the New York Academy of Medicine (fig. 14) is in a very particular sense of interest to ophthalmologists. It was Dela-

field (fig. 15) who conceived the idea of an academy and it was he who became its first president. Rodgers (fig. 16) was one of its incorporators, and at his funeral, in 1851, the Academy attended

Fig. 15 (Samuels). Edward Delafield.

in a body. The Section of Ophthalmology is one of 12 sections into which the Fellows of the Academy are divided. In 1885, ophthalmology and otology were combined to form one section. At the breaking up of this dual relationship, in 1900, the regular meeting night, the third Monday of the month, fell to ophthalmology and so it has been these 62 years. Almost the first act of the dual section was to appoint a committee to ascertain the number of books on these specialties in the library. The committee reported 160 books on the eye and 40 on the ear. Today the eye books and monographs number about 2,500 and on the racks are to be found some 30 current journals on this subject. The library of the Academy ranks second in size to that of the Sur-

geon General's in Washington. It contains many old and rare books on the eye. It is the repository of the minutes of the American Ophthalmological Society and the New York Ophthalmological Society.

In spite of every facility for access to books that the Academy offers, New Yorkers vie with one another in collecting and possessing their own books. Notable are the fine libraries owned by Arnold Knapp, Ralph Lloyd, and Conrad Berens.

An invitation to become a Fellow of the Academy is an honor not to be taken lightly. This is the forum in which the Fellows from all the eye hospitals gather to present cases, read papers, and discuss the medical affairs of the day. Here distinguished guests are received and

Fig. 16 (Samuels). John Kearny Rodgers.

entertained. Many associations endear these walls to us. Here, as death takes its toll, the work and measure of each Fellow is reverently recounted. In the midst of

this high celebration we should not be unmindful of those who, although not of our calling, have made this imposing fabric possible and have looked after the material concerns of hospitals and clinics through the years.

In the progress of this paper on "New York as an Ophthalmological Center" it came to me as a surprise that nowhere is there vaster clinical material; nowhere

is there more or better surgery; nowhere greater facilities for teaching; and nowhere are there so many incentives for research work. I trust that I am not too indulgent when I venture to express the opinion that in no metropolis in the world is the art and science of ophthalmology more sedulously cultivated than in New York.

57 West 57th Street (19).

DICUMAROL AND RUTIN IN RETINAL VASCULAR DISORDERS*

ANGUS L. MACLEAN, M.D., AND CHARLES E. BRAMBEL,[†] PH.D.

Baltimore, Maryland

INTRODUCTION

Two retinal vascular problems confront the ophthalmologist: (1) Hemorrhage following capillary weakness. (2) Occlusion as the result of thrombosis, periphlebitis, atherosclerosis or constriction. Today, chemotherapeutic agents are available which show promise for alleviating some of these conditions. In-vivo anti-coagulants (heparin and dicumarol) for inhibiting the thrombotic process and preparations possessing vitamin-P properties (hesperidin and rutin)[‡] for decreasing capillary fragility are being subjected to critical clinical evaluation. It is the purpose of this report to present the concomitant use of these two groups of chemical substances in vascular retinopathies.

Since obstruction of the retinal veins was first described by Julius v. Michel in 1878,¹ the matter has been the subject of almost continuous research, but even today many points, both in the etiology and the intimate mechanism of the obstruction, are still unelucidated. The general mechanism of the occlusion is somewhat complicated depending usually upon events both in the arterial and the venous parts of the circulation.

Duke-Elder² has described four stages in the mechanism of retinal venous occlusion:

(1) A slowing of the blood flow which is a necessary prelude to thrombosis. This process is usually determined by events occurring in the arteries and veins. The entrance flow may be diminished owing to a general loss in vascular tone, or frequently to mechanical constriction at the lamina cribosa by the proliferation of the surrounding connective tissue. The net result is an impedance of arterial flow and a damming back of venous return.

(2) The formation of a roughened area on the endothelium. The roughening may be due to simple atheromatous enlargement of the adjoining artery causing indentation of the vein and trauma to its

* From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University and the Department of Clinical Biochemistry, Mercy Hospital, Baltimore, Maryland. Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

[†] By invitation.

[‡] The Abbott Laboratories, North Chicago, Illinois, generously supplied the rutin and hesperidin used during the course of this investigation.

endothelium. Most commonly, however, it is an expression of an endophlebitis of systemic origin for which no particular toxin but probably a large number must be held responsible.

(3) Upon this area cells and fibrin are deposited so that a nodule or organized thrombus protrudes into the lumen of the vein. The thrombus grows by accretion in the relatively stagnant blood stream until the lumen is reduced to a mere slit and the local circulation brought almost to a standstill.

(4) Verhoeff³ considers that thrombosis in the true sense is exceedingly rare, but that it is the proliferative activity of the vein endothelium which continues to build up a nodule which similarly gradually fills the lumen. A review of the current evidence reveals that such a process appears unlikely since obliterative endothelial proliferation in veins has not been established histologically.

Heparin⁴ has been used in retinal venous occlusion for short periods with encouraging results. However, there appears to be some disagreement as to the efficacy of this anticoagulant therapy.⁵ Dicumarol 4-g has likewise been used to a limited extent. It is our purpose to present the clinical application of anti-coagulant administration for long periods to ambulatory patients.

Dicumarol (3-3) Methylene-bis (4-Hydroxycoumarin) is a compound found in spoiled sweet clover which has been known to produce a hemorrhagic disease in cattle. It was isolated from spoiled sweet clover and later synthesized by Link⁶ and his associates at the University of Wisconsin. When dicumarol is administered orally, the prothrombin activity of the blood is reduced⁶ and intravascular thrombosis,⁷ as well as intravascular coagulation, is inhibited.

No evidence is available that damage to the endothelial lining is incurred dur-

ing controlled treatment with dicumarol. The factors involved in capillary bleeding are still obscure and the subject of many conjectures.

Anticoagulants may be used for inhibiting the conversion of fibrinogen to fibrin. In this manner the enlargement of the clot by continued fibrin deposition may be prevented. The performed thrombus, if its growth is checked, may in a number of instances retract, leaving a lumen for the passage of blood. Substances manifesting antipurpuric properties⁸ (rutin⁹ and hesperidin¹⁰) were used to decrease capillary fragility when present.

CLINICAL MATERIAL

The present series includes 21 cases of a number of vascular retinopathies observed in private practice (table 1); that is, tributary occlusion, two; central vein occlusion, partial, six; diabetic retinopathy, four; degenerative retinopathy, five; central serous retinopathy (angiospastic), two; and Eales' disease, two. The age of the patients varied from 34 to 72 years. With the exception of the two patients with Eales' disease (who were placed on rutin administration alone), all the patients received dicumarol ranging from 4 to 40 weeks' duration. The two cases of tributary thrombosis were placed on dicumarol alone,* while the remainder of the patients were subjected to concomitant administration of rutin and dicumarol. Detailed ophthalmoscopic examination of the patients was made periodically during the course of treatment with dicumarol and rutin.

RATIONALE

Premonitory signs of vascular retinopathies are not often recognizable, and hence the initial process cannot be prevented. Four processes are involved:

* Rutin was not available at that time.

hemorrhage, thrombosis, atherosclerosis and exudative congestion. These will be considered under three general headings: (1) Thrombosis primary and hemorrhage secondary; (2) Hemorrhage primary and thrombosis secondary; and (3) Degenerative retinopathy.

THROMBOSIS PRIMARY—HEMORRHAGE SECONDARY

Thrombosis results in building up of the back pressure with engorgement of vessels with blood. The consequence of this condition is a rupture of the vessels from the breakdown of vessel wall elasticity, giving rise to hemorrhagic areas. Secondary thrombosis in the damaged capillaries may take place as a protective mechanism. This thrombotic process may progress and contribute to the existing pathologic picture resulting in a decreased vascular efficiency.

Under such circumstances dicumarol or other in-vivo anticoagulants to inhibit the existing thrombotic tendencies would be indicated. Also, rutin or other vitamin-P-like substances would be therapeutically indicated to improve capillary integrity. The clinical conditions encountered in this category are tributary occlusion and central-vein occlusion, partial or complete.

HEMORRHAGE PRIMARY—THROMBOSIS SECONDARY

When hemorrhage is the primary cause of the retinopathic state, two general clinical conditions must be considered: Hypertension and idiopathic capillary weakness giving rise to recurrent hemorrhages. In hypertension there may be a sudden increase in blood pressure together with an increased capillary fragility¹⁰ frequently attendant with this condition. The vessel walls rupture, giving rise to a hemorrhagic area. Here again, secondary thrombosis occurs in

the damaged capillaries as a protective mechanism and contributes to the existing pathologic picture.

Under these circumstances, rutin or other vitamin-P-like substances to improve capillary integrity would be therapeutically indicated. In a number of cases the Gothlin Index¹⁰ of capillary fragility is also increased. Dicumarol cautiously and conservatively administered would be indicated to inhibit differentially the thrombotic processes involved (about 60 percent of normal prothrombin activity). This routine of concomitant administration of these two drugs should increase the rate of absorption of the hemorrhages, and the possibility of new ones should be reduced.

In Eales' disease, where recurrent hemorrhages of questionable etiology occur, the same therapeutic indications should apply.

The use of anticoagulants should not exaggerate the existing hemorrhagic picture provided the above-mentioned conditions are meticulously observed. It is to be realized that experience, discretion, and satisfactory methods for the control of the coagulation system are of utmost importance.

DEGENERATIVE RETINOPATHY

Here one encounters an idiopathic, impaired vascular efficiency resulting in localizing degenerative and proliferative processes with exudative congestion.² Localized capillary occlusion or angiospasm may be the contributing factors. Administration of dicumarol or other in-vivo anticoagulants to inhibit thrombotic tendencies or cellular adhesiveness should facilitate circulation. Rutin or other vitamin-P-like substances to improve capillary integrity would also be therapeutically indicated.

Administration of adequate amounts of anticoagulant may prevent extension of

the thrombus. For economical reasons, and because of the ease of administration and control, dicumarol was selected as the anticoagulant of choice. While heparin institutes an immediate effect, its administration raises practical difficulties.

METHODS

Prothrombin clotting-time determinations have been done by Quick's¹¹ method using a modified standardized thromboplastic reagent as described by Brambel:¹²

"Four and one-half cubic cm. of freshly drawn blood was introduced into a graduated centrifuge tube containing 0.5 cc. of tenth-molar solution of sodium oxalate. The tube was inverted several times and centrifuged to obtain clear plasma.

"In the performance of the test, 0.1 cc. of clear plasma was placed in a small tube, to which 0.1 cc. of modified thromboplastic reagent was added. After thorough shaking of the contents, 0.1 cc. of 0.025 molar solution of calcium chloride was added to the mixture. A stopwatch was started and the tube placed immediately in a water bath adjusted to 37.5°C., in which it was tilted back and forth until the formation of a firm clot was observed. Normal undiluted plasma coagulated in thirteen to fifteen seconds.

"Five-tenths cc. of clear, oxalated plasma was added to 3.5 cc. of 0.85 percent saline solution to obtain a 12.5 percent dilution. One-tenth cc. of this diluted plasma was pipetted into each of two small tubes. Thromboplastic reagent and calcium chloride solution (0.1 cc. each) were added to each one, and both tubes were placed in the water bath. They were tilted back and forth until a web clot appeared at the rim of the meniscus. Normal 12.5 percent plasma clotted in eighty-five to ninety-five seconds. Usually, the two tubes showed a web clot simultaneously, but if small variations occurred, the two values were averaged."

Several investigations¹³ have shown that variations of prothrombin activity can be better detected with diluted plasma, particularly for demonstrating increased activity of the clotting components.

All of our cases manifested an increased prothrombin activity; that is, decreased prothrombin clotting time of 12.5-percent plasma. This finding has been interpreted as a manifestation of an enhanced clotting tendency of the blood of these patients compared to normal and is attendant with retinopathies rather than the cause of them.

The Petechial Index of Gothlin was determined by the method modified by Griffith and Lindauer:¹⁰ "Technique of the Test: (1) Mark off a circular area, 6 cm. in diameter, in each antecubital area. Mark off all blemishes and marks in this area that might be confused with petechiae; (2) place a standard blood pressure cuff about each arm, and maintain in each a pressure of 35 mm. of mercury for 15 minutes. Lower the pressure and count and mark all petechiae within the two circular areas, using a good light and a magnifying lens of 5D or its equivalent; (3) one hour or more later, repeat, using a cuff pressure of 50 mm. of mercury.

"The Petechial Index is calculated as follows: To the number of petechiae occurring at 35 mm. of mercury multiplied by 2, add the additional number occurring at 50 mm. Based upon the Petechial Index, capillary fragility is considered to be: (a) normal, if the index is 8 or less, (b) increased (abnormal), if the index is 13 or more, and (c) borderline, but probably abnormal, if the index is 9 or 12."

DOSAGE

No patient should be given dicumarol unless adequate laboratory facilities are available to check the prothrombin clotting time with appropriately standardized reagents. Otherwise, hazardous difficulties

may arise from failure to reproduce the desired depression of prothrombin activity. Experience and good judgment are essential in estimating dicumarol dosage on the basis of response of the coagulation system to the drug. Dicumarol was administered orally.

An initial prothrombin clotting-time determination was made on each patient before dicumarol administration was begun. The first dose was 300 mg. In view of the experience with a number of cases by one of us (C. E. B.) (now totaling 2,500) the next test was run in 48 hours, since the maximum effect of any given dosage is obtained after a period of 36 to 48 hours. In this manner the hyperreactors can be detected before the cumulative effect of several doses is manifest.

A series of subsequent determinations were made at two-day intervals with dosages of 100 to 300 mg. to maintain a coagulation activity level of 50 percent of normal (never exceeding a prothrombin clotting time of 30 seconds for undiluted plasma).

After it was satisfactorily demonstrated that the patient was not a hyperreactor and the response could be fairly well predicted, the patient was continued on dicumarol, returning to the clinic once a week for prothrombin clotting-time determinations and succeeding doses.

Although this procedure has been used with success in this series of cases, it is not generally recommended and, indeed, it is not without hazard unless complete coöperation of the patient, his physician, and the laboratory is obtained. For example, in the event of increased body temperature or kidney involvement following administration of other concomitant drug therapy, dangerous and unpredicted depression of prothrombin activity may be the consequence. Too much emphasis cannot be placed on this consideration.

Concomitant oral administration of rutin in 60-mg. daily doses was the usual routine and was kept up for the duration of the combined therapy. The patients were periodically checked for evidence of capillary fragility by the Gothlin test.¹⁰ In some selected cases, 125 mg. daily were given.

TOXIC EFFECTS

The two chemotherapeutic agents used in this series of cases presented minimal untoward side reactions. Reports in the literature reveal that dicumarol⁷⁻⁹ and rutin⁹ have been administered continuously for a period up to 2½ years without delayed toxic reactions.

Several investigators¹⁴ have shown that dicumarol does not disturb the formed elements of the blood, nor does it affect the capillary fragility and clot retraction when conservatively administered. Evidence has been presented¹⁵ that capillary damage may result when excessive amounts of this anticoagulant are used. The blood coagulation time is altered only after prothrombin activity is reduced beyond 50 percent of normal. Undesired or excessive hypoprothrombinemia, should it occur, can be controlled¹⁶ by the intravenous injection of 37.5 mg. of menadione bisulfite (72 mg. hykinone) or by fresh blood transfusion.

Notwithstanding the reports of a fairly substantial percentage of hemorrhagic incidents in some clinics,¹⁷ only one patient in this series of 21 cases manifested transitory frank hematuria and none showed microscopic hematuria. The explanation may be found in the fact that conservative administration of this anticoagulant to ambulatory patients was meticulously carried out. Occasional nausea or headache and a mild diarrhea (usually after the first dose) were the only immediate side effects noted. These disturbances were easily controlled.

The induced hypoprothrombinemic

state did not involve permanent functional impairment of the liver. On the contrary, return to a normal state of prothrombin activity within 72 hours was observed following cessation of dicumarol dosage regardless of the length of the period of administration. Pharmacologic and toxicologic investigations¹⁸ support these findings.

No toxic manifestations were observed

nite decrease in the prothrombin clotting time of dilute plasma compared to normal controls. These observations together with the ophthalmoscopic findings served as the basis for anticoagulant therapy.

In over half of the cases, rutin or hesperidin was administered as prophylaxis for possible capillary weakness. However, increased capillary fragility, as determined by the Gothlin Index, was positive

with rutin. Repeated analysis of clinically significant components of blood chemistry and cellular elements showed no deviation from normal as a consequence of the use of this drug.

DISCUSSION OF RESULTS

The present series of cases of various retinopathic conditions manifested a defi-

only in cases of idiopathic hemorrhagic disease (Eales' disease).

The thesis that in-vivo coagulation-activating substances may be liberated in the blood stream is suggestively supported by the results obtained from anticoagulant administration by depressing the activity of one of the major components of the blood coagulation system; that is,

prothrombin. The interpretation of the pathology of the various retinopathic conditions presented in this paper is based on derangement of the blood coagulation system involving vascular efficiency.¹⁹

CASE REPORTS

TRIBUTARY OCCLUSION

The two cases of tributary occlusion (table 1, cases 1 and 2) showed an increased rate of improvement in visual acuity with disappearance of hemorrhages and exudates during treatment with dicumarol. No recurrence of symptoms was noted.

Case 1. Tributary occlusion of upper temporal vein. J. S. E., a 45-year-old white man, upon clinical examination in January, 1945, revealed hemorrhage and edema from the upper temporal vessels to the macula in the right eye involving tributary occlusion of the upper temporal vein. The vision at this time was 20/100. No improvement was noted for four months.

On April 23, 1945, the vision was still 20/100 when anticoagulant therapy was started. The initial prothrombin clotting-time determination showed a marked decrease in the clotting interval for diluted plasma; that is, 65 seconds (normal 85 seconds). After an initial dose of 300-mg. dicumarol, the prothrombin was altered only slightly, indicating a mildly refractory nature of the coagulation system. This patient required 600 mg. weekly in 200-mg. doses every two days. Dicumarol administration was continued for seven weeks with the prothrombin mechanism reduced to approximately 50 percent of normal when compared with standard dilution curves.

In May, 1945, ophthalmoscopic examination revealed that the hemorrhage was absorbing slowly and the vision was 20/40. An examination in September, 1945, revealed that absorption of the

hemorrhage was practically complete and the vision was 20/20. A wedge-shaped sector at the macula was the last to absorb. In February, 1946, some pigmentary atrophic changes were noted with whitish lines and tortuous vessels in the area that had been involved. No hemorrhagic manifestations were visible.

Comment. This patient showed very slow improvement during the four months preceding anticoagulant therapy, vision in the right eye remaining 20/100. Marked clinical improvement was noted after dicumarol administration was started, and vision in the right eye increased to 20/20. After cessation of the therapy, vision continued to improve to normal and has continued so to the present time without anticoagulant therapy.

CENTRAL-VEIN OCCLUSION

The rate of recovery of visual acuity and absorption of hemorrhages and exudates in the six cases of central-vein occlusion (table 1, cases 3-8; see figs. 1 to 3) was somewhat variable. There is some indication that ophthalmoscopic changes occur more rapidly in the older age group (notwithstanding the complication of arteriosclerosis) than in younger patients.

No satisfactory theoretical or practical explanation for this observation can be advanced at this time. Three of the six cases in this group were placed on rutin as prophylaxis for capillary weakness. The Gothlin Index for capillary fragility was normal in all of these patients. The clinical course of the patients on concomitant therapy was to all practical purposes identical with those on dicumarol alone.

Case 3. Occlusion of central retinal vein, partial. Moderate retinal arteriosclerosis. C. M. H., a 72-year-old white man, upon clinical examination of the eyes revealed moderate retinal arteriosclerosis. There was partial occlusion of the central

retinal vein of the right eye with hemorrhages and exudates in the temporal half of the retina. In November, 1944, the vision was 20/200. Eight months later an examination revealed fewer hemor-

1945, a period of six months. For four months the prothrombin activity was maintained at about 50 percent of normal with dicumarol requiring about 500 to 600 mg. per week. The patient tolerated the

(A) is a view showing optic nerve and surrounding area with venous engorgement, many large hemorrhages and extensive edema. (B) is a view of the macular and perimacular area showing large blotchy retinal hemorrhages. Hemorrhage and edema obscures the clear view of the retinal vessels. Vision 20/400. (C and D). Retinal photographs taken three months after beginning of treatment with dicumarol and rutin. (C) is the same area as (A), still showing venous engorgement, but hemorrhages are smaller and some absorption has taken place. (D) is the same area as (B), showing some absorption of retinal hemorrhages and a clearer view of retinal pattern. Vision 20/100.

rhages and edema with the vision 20/100.

A determination of prothrombin activity on June 20, 1945, showed a decrease in the clotting time of diluted plasma. Dicumarol administration was started on this date and terminated October 20,

anticoagulant without any side reactions.

The patient was examined ophthalmoscopically in September, 1945. Vision of the right eye was 20/40, and only a few remaining hemorrhages above the macula were found. Slight macular edema was

Fig. 2 (MacLean and Brambel). *Case 7. Central vein occlusion.* (A). Retinal photograph taken before beginning of treatment with dicumarol and rutin. The appearance of the fundus showing engorged veins, hemorrhages and exudates. Vision 20/200. (B). Retinal photograph of same eye taken eight weeks after beginning of treatment with dicumarol and rutin. Only few hemorrhages remain. Vision 20/40. (C). Retinal photograph of same eye taken 10 weeks after beginning of treatment with dicumarol and rutin. The veins have returned to normal size and hemorrhages have practically all absorbed. Vision, 20/30.

noted and the foveal reflex was fair. In December, 1945, vision of the right eye was 20/20, and the retina was completely clear. On May 24, 1946, vision of each eye was 20/20. Ophthalmoscopic examination showed some newly formed tortuous vessels in the right eye above and below the macula. The veins were no longer engorged or enlarged and no hemorrhages were present. A determination of prothrombin activity at this time again revealed a decrease of the clotting time of dilute plasma.

Comment. This patient showed very slow improvement during the eight months preceding anticoagulant therapy. Clinical improvement was more marked after dicumarol administration. The use of anticoagulants was indicated by the increased clotting tendency as manifested by the shortened prothrombin time of diluted plasma. It is of special interest that retinal vascular improvement was noted when the coagulation mechanism was disrupted to 50 percent of normal for four months in an arteriosclerotic patient. There was no evidence of peripheral capillary weakness at any time,

DIABETIC RETINOPATHY

Some of the etiologic factors in diabetic retinopathy may be attributed to vascular sclerosis.² In this respect the use of a readily controlled anticoagulant administered for an indefinite period of time should be helpful in eliminating thrombotic conditions and tendencies associated with the disease.

Four cases of diabetic retinopathy (table 1, cases 9-12; see fig. 4) showed improvement of visual acuity and absorption of hemorrhages when treated with dicumarol. No increase in capillary fragility was observed in this group of patients. However, two of four patients were placed on rutin administration simultaneously with dicumarol. Here again, as noted above, the clinical course of the two sets of patients was identical.

The only logical explanation for ophthalmoscopic improvement in our series of diabetic retinopathic patients probably lies in the fact that thrombotic tendencies were inhibited by the anticoagulant with resulting increased vascular efficiency followed by clearing of the involved retina. Also, it is of special significance that

no recurrence of symptoms was noted during course of therapy. The interpretation of this clinical condition on the basis of other etiologic factors must not be minimized. Our present series of cases

and tortuous macular arterioles. There was some edema and exudation in the macular area. Vision in the right eye was 20/50; left eye, 20/20.

A determination of the prothrombin

Taken one month after beginning of treatment. A large flame-shaped hemorrhage is seen below the disc along the course of the lower temporal vessels. Vision. 20/400. (C and D). Retinal photographs taken six months after beginning of treatment with dicumarol and rutin. Views of same areas corresponding to (A) and (B). Practically all the hemorrhages have absorbed. A clearer view of the retinal pattern is obtained showing less venous engorgement. Vision: 20/50.

is too small, and final critical evaluation must await findings from larger numbers.

Case 9. Diabetic retinopathy. Arteriosclerosis, Grade 2. Scattered retinal hemorrhages and exudates. A. C., a 68-year-old white man, with mild diabetes and arteriosclerosis revealed upon ophthalmoscopic examination in November, 1945, scattered pin-point retinal hemorrhages

activity on November 20, 1945, showed a decrease in the clotting time of dilute plasma (56 seconds compared to 85 seconds for the lower limit of normal). Dicumarol administration was started on this date and has been continued without interruption to the present date. This patient has been on continuous anticoagulant administration for eight months with

his prothrombin activity reduced to about 50 percent of normal. The average dicumarol requirement to maintain this level was 300 mg. per week, 100 mg. being taken on alternate days. A total of 5,800

rhages and exudates were observed. On April 15, 1946, the right eye was entirely clear of hemorrhages and exudates in the periphery. Some edema and a few fine pin-point hemorrhagic dots were still

Fig. 4 (MacLean and Brambel). *Case 10. Diabetic retinopathy.* (A and B). Retinal photographs taken on same day three months after beginning of treatment with dicumarol and rutin. Scattered hemorrhages and exudates are seen. (C and D). Retinal photographs of same eye six months after beginning of treatment with dicumarol and rutin. Some absorption of hemorrhages is seen. Vision 20/50.

mg. dicumarol has been administered.

On February 23, 1946, capillary fragility, as determined by the Gothlin test, was negative. However, 40-mg. rutin daily were given orally and continued as of the present date. Rutin was used in this case as prophylaxis for potentially increased capillary permeability.

In March, 1946, vision in the right eye was 20/30; left eye, 20/20. Fewer hemor-

present in the lower part of the macula.

Comment. This patient presenting mild diabetes and arteriosclerosis Grade 2, with scattered peripheral pin-point hemorrhages and generalized edema and exudation in the macula showed some improvement after six months of anticoagulant therapy. The use of anticoagulants was indicated by the increased clotting tendency as manifested by the shortened

prothrombin time of diluted plasma. Although there was no evidence of peripheral capillary weakness, rutin therapy was instituted as prophylaxis. There was slight improvement in vision and gradual but progressive clearing of hemorrhages and exudative processes.

SPASM OF CAPILLARIES

The retinopathic condition manifested by macular and premacular edema with attenuated vessels may be the result of spasm of the capillaries or toxic processes of an allergic etiology.² Two such cases

pairment to explain the clinical condition. This idea is supported by the finding that in a very short time on concomitant anticoagulant and rutin therapy the lesions cleared and normal visual acuity was restored. It is suggestive to presume that toxins in some manner were rendering the capillary beds inefficient, resulting in edema. Also, there may have been some obstruction of capillaries with soft clots. But with the increase in capillary efficiency the inflammatory condition subsided.

It is to be borne in mind that the

A

B

Fig. 5 (MacLean and Brambel). *Case 18. Central serous retinopathy (angiospastic)*. (A). Retinal photograph of left eye one week after beginning of treatment with dicumarol and rutin. Shows marked attenuation of branch of inferior temporal artery leading to macular area and milky white appearance with edema in and below the macula in lower part of the macula supplied by this vessel. Vision 20/40. (B). View of same eye two weeks after beginning of treatment with dicumarol and rutin showing retinal vessel slightly larger with some absorption of edema. Vision 20/30.

(table 1, cases 18-19; see fig. 5) are presented in our series. Ophthalmoscopically both patients showed impaired visual acuity and the other usual signs and symptoms of this condition. Ordinarily, prognosis is relatively favorable in such cases provided the symptoms are of short duration. Both patients were started on combined therapy within a short time after onset.

It is tempting to presuppose that the finding of a decreased clotting interval of diluted plasma compared to normal was a premonitory sign of vascular im-

number of cases is small and further follow-up studies and additional patients will have to be analyzed before a definitive clinical evaluation is possible. It is of special interest that neither dicumarol nor rutin contributed to the toxic condition.

Case 19. Central serous retinopathy (angiospastic). M. M., a 35-year-old white man, upon ophthalmoscopic examination in January, 1946, showed in the right eye an annular swelling surrounded by a ring-shaped light reflex in the macular area and marked narrowing of one of the main arterioles leading to this area.

The vision, which commenced to blur three days previously, was 20/70.

Prothrombin clotting-time determination revealed a decreased clotting interval of diluted plasma. Dicumarol administration was started and the prothrombin activity was maintained at 50 percent of normal for three months. Rutin (60 mg. daily) was given for the last two months.

Comment. In three months the edema subsided. The attenuated arteriole was larger and more normal in appearance, and the vision was 20/20. Five months after onset there have been no further recurrences and medications have been discontinued.

EALES' DISEASE

Two cases of recurrent idiopathic retinal hemorrhage² (Eales' disease) (table 1, cases 20-21) are presented in this series. These patients manifested a strongly positive Gothlin Index. Rutin alone was the drug of choice. Following administration of this flavonal glucoside, improvement in visual acuity corresponded to restoration to normal of capillary weakness.

Case 20. Eales' disease. Perivasculitis with recurrent vitreous hemorrhage and uveitis. E. P., a 60-year-old woman, in June, 1944, developed iridocyclitis in the left eye. View of the fundus was obscured by the vitreous haze. When this cleared, she was found to have a large, whitish chorioretinal lesion temporal to the macula with much perivascular sheathing of the adjoining retinal vessels. There was a mild generalized arteriosclerosis, with the blood pressure 170/95 mm. Hg. Previously, there was a chronic cholecystitis which later became acute, necessitating an emergency cholecystectomy. The intracutaneous tuberculin test was markedly positive up to 1:1,000,000 dilution. She was given tuberculin therapy. There were mild recurrences of the

inflammatory reaction and vitreous haze for almost a year.

In October, 1945, a similar condition developed in the right eye and for five months the clinical course was characterized by recurring attacks of vitreous hemorrhage and uveal inflammation followed by slight clearing of the media with improvement in the vision. In March, 1946, the vision was down to 2/200, and all fundus details were obscured by the vitreous haze. Capillary fragility, as measured by the tourniquet test, was found to be markedly positive. Rutin (60 mg. daily), was started. Following this, improvement was almost dramatic. There was no more vitreous hemorrhage and the existing opacity cleared and absorbed rapidly with vision back to 20/30 in three weeks' time.

Comment. This patient responded very favorably to rutin administration with clearing of vitreous and retinal hemorrhages. It is tempting to presume that the effect of the rutin was to improve capillary integrity sufficiently with the result that an efficient capillary bed in the retina was formed whereby absorption of hemorrhage and vitreous cloud was facilitated.

DEGENERATIVE RETINOPATHIES

The primary etiologic factors for degenerative retinopathies (table 1, cases 13-17; see fig. 6) probably rest upon vascular sclerosis.² Anticoagulant therapy should forestall the secondary process of thrombosis. Improvement of visual acuity has been uniformly obtained in all the patients in this series. Evidence is presented which indicated that anticoagulants have to be administered continuously for an indefinite period of time since cessation of anticoagulant therapy results in regression of symptoms. How advantageous and efficacious such a course of therapy will be remains to be established

by further ophthalmic study. These findings open a new field of research into degenerative vascular retinopathies.

Case 13. Disciform retinal degeneration, bilateral. E. H., a 56-year-old

generative macular lesion about a disc diameter in size having the appearance of an arrested Junius Kuhnts' type of degenerative retinitis. The vision was 1/200 eccentric.

A

B

C

D

Fig. 6 (MacLean and Brambel). *Case 13. Degenerative retinopathy.* (A). Retinal photograph of right eye taken one month after beginning of treatment with dicumarol and rutin. This view shows early disciform central retinal degeneration with hemorrhage. Some absorption has taken place. Vision 20/100. (B). Same area as Figure 6A but taken four months after beginning of treatment. Vision 20/40. (C). Same area as Figure 6A but taken six months after beginning of treatment with dicumarol and rutin. woman, noticed blurring of vision of the right eye about three weeks before treatment was started. There was a circumscribed hemorrhagic lesion in the macula, and vision was 20/100.

Five years previously she had what she described as a hemorrhage in the left eye. There was a circumscribed, white, de-

Treatment with dicumarol was started on November 19, 1945, and continued until May 16, 1946. Rutin (60 mg. daily) was started on January 13, 1946, and is still in progress. Prothrombin activity has been maintained at 50 percent of normal, requiring 300-500 mg. per week.

In three months' time the hemorrhage

had cleared from the central macular area, leaving a small crescent-shaped area below the fovea, and the vision had improved to 20/30. In another three months the lesion had cleared entirely and dicumarol administration was discontinued, but rutin therapy was kept up.

One month following the discontinuance of the anticoagulant the vision was again down to 20/70, an ophthalmoscopic examination showed recurrence of macular hemorrhage. Administration of dicumarol was resumed and to date there has been noticeable improvement with the vision 20/50. Ophthalmoscopically, the macular hemorrhage is absorbing. At present, a small crescent-shaped hemorrhage remains below the fovea and there are some pigmentary and cystic changes.

Comment. This patient responded favorably to anticoagulant therapy and when it was discontinued, regression of vision and recurrence of lesions took place. This case illustrates the necessity and efficacy of long-term anticoagulant administration in degenerative types of retinopathy.

CONCLUSIONS

The validity of our conclusions—that dicumarol and rutin possess therapeutic value in venous thrombosis and the absorption of retinal hemorrhages—depends on the admission that the rate of absorption of such blood extravasations in

the patients here reported was greater and more rapid than could have been observed had no treatment been given. Without clinical or laboratory controls, it is obviously impossible to verify this point. It was our opinion, however, that the absorption of the hemorrhages was decidedly more rapid than could have been expected in untreated cases. Especially is this true in the diabetic cases reported.

1. Long-term administration of dicumarol has been used efficaciously in central and tributary retinal occlusion, diabetic, degenerative, and central serous retinopathies.

2. Rutin has been found to decrease capillary fragility and has been used with benefit in recurrent retinal and vitreous hemorrhage.

3. An increased clotting tendency has been observed in all our cases of vascular retinopathies. This is manifested by a decrease in the prothrombin clotting time for diluted (12.5 percent) plasma.

4. Improvement in visual acuity has been accomplished in this series by maintaining the prothrombin activity between 50 and 60 percent of normal up to a period of six months or more.

5. Sufficiently significant results have been obtained to warrant further clinical evaluation of dicumarol and rutin in ophthalmology.

RECESSION OF LIMBAL CONJUNCTIVA

AN OPERATION FOR TREATMENT OF TRACHOMATOUS PANNUS

M. LOMBARDO, M.D.

Brooklyn, New York

Trachoma, still a widespread disease, a personal or family stigma, a social plague where prevalent, is always an interesting subject, however considered. Early superficial pannus and its accompanying ulcers make the sufferer an invalid for recurrent periods of time, and its degeneration into the thick, persistent, and richly vascular pannus of the entire cornea causes severe impairment of vision, and, if equally developed in both eyes, produces chronic, perennial invalidism. The treatment of pannus varies from the local application of drugs to the simple, conservative, or more or less radical operative procedures.

I would like to describe herewith a surgical method which I have been performing in severe and persistent cases of the disease.

OPERATIVE PROCEDURE

A lid speculum, two fixation forceps, a double fixation forceps, a curette, a cataract knife, a needle holder, and six double-armed sutures of No.-3 braided silk are needed for the operation.

Infiltration anesthesia of lids and upper and lower fornices is usually sufficient. General anesthesia is employed in unruly patients.

After the usual preoperative local preparations have been made, the speculum is inserted and the conjunctiva is circumcised as close to the limbus as possible (fig. 1) and then dissected all around to the limits of the fornices (fig. 2). The subconjunctival tissue is now carefully removed for about 6 mm. around the limbus, leaving a bare, clean sclera. The remnant of the conjunctiva at the limbus

is curetted away, and the blood vessels in the cornea still full of blood are split with the point of a cataract knife. The specu-

Fig. 2 (Lombardo). The conjunctiva is then dissected all around to the limits of the fornices.

lum is now removed and a suture is applied as shown in Figure 3-C, using the following procedure.

While the upper section of the con-

junctiva is held and everted by a double fixation forceps (fig. 3-a) one needle of the double-armed silk suture is inserted in the scleral side of the conjunctiva at

Fig. 3 (Lombardo). Suturing technique in the operation of recession of limbal conjunctiva.

about 10 mm. from its margin (fig. 3-b), passed parallel to it for about 6 mm. without perforating the membrane, is brought upward between the conjunctiva and the sclera (fig. 3-C) and then out through the skin below the brow (fig. 3-D). The other end of the suture (fig. 3-e) is carried up and brought out near the first end, care being taken that the two ends of the suture come out in a converging direction. The ends of the suture are now pulled out making traction on the cut margin of the conjunctiva until this is recessed to about 6 mm. from the limbus and are then knotted on a small roll of gauze. The same procedure was followed on applying all sutures.

Figure 3, at A and B, shows the su-

tures properly inserted in upper lid and the conjunctiva recessed from the limbus upward, as well as the two ends of each suture knotted on the roll of gauze below the corresponding section of the brow.

Figure 3, at D, E, and F, shows three other equidistant sutures inserted similarly in the lower section of the conjunctiva and brought out near the corresponding lower margin of the orbit. Figure 3 also shows, at G, how the incised margin of the conjunctiva has been recessed all around at an even distance from the cornea.

After all sutures are applied the conjunctival sac is irrigated with bichloride of mercury solution (1:5,000). Bichloride of mercury ointment (1:5,000) is applied, and the eye is bandaged. The eye is

Fig. 4 (Lombardo). The appearance of the eye after the sutures have been removed.

dressed every day, and the sutures are allowed to remain in place until the sclera is seen to be covered by epithelium.

The resulting appearance of the eye after the removal of the sutures is represented by Figure 4.

DISCUSSION

Recession of conjunctiva to treat pannus consists essentially in the permanent fixation of the incised limbal margin of conjunctiva away from the cornea. It is a new operative method based on the principle that the abnormal blood vessels of the cornea are to be properly and per-

hyperplastic limbus. The advancing terminations of the small vessels appear to be surrounded by a grayish infiltration of lymphatic elements or to converge towards zones of avascular infiltration. These observations lead one to think that blood vessels either represent the originator, the prime pathogenic manifestation,

TABLE 1

RESULTS OBTAINED FROM THE RECESSION OF LIMBAL CONJUNCTIVA FOR
TREATMENT OF TRACHOMATOUS PANNUS

Case Number	Sex	Age of Patient	Eye Operated	Form of Pannus	Vision Before Operation	Vision After Operation	Condition of Cornea After Operation	Inflammatory Relapse
1	M	23	L	Densely vascular	5/200	20/70	Only faint thin opacities remain affecting the corneas and their pupillary areas, which, becoming more or less transparent, make the vision of these eyes restored in proportion.	None
2	F	34	R	Densely vascular	L.P.	20/100		None
			L	Densely vascular	c.f. at 3 feet	15/200		None
3	M	28	R	Slightly vascular	10/200	20/70		None
4	M	29	R	Densely vascular	L.P.	20/100		None
			L	Slightly vascular	8/200	20/100		None
5	F	26	L	Thickly vascular	L.P.	10/200		None
6	F	32	R	Slightly vascular	c.f. at 3 feet	20/70	Only faint thin opacities remain affecting the corneas and their pupillary areas, which, becoming more or less transparent, make the vision of these eyes restored in proportion.	None
			L	Slightly vascular	10/200	20/100		None
7	M	34	R	Slightly vascular	10/200	20/50		None

manently eliminated in order to cure the pannus.

Biomicroscopic observations on beginning trachomatous pannus by M. Vele, A. Busacca and others reveal the presence of capillaries running in the superficial layers of the cornea mostly in the upper section of this structure. The capillaries are seen to spring from the blood vessels of the conjunctiva and to reach the cornea through a somewhat

and the nutritive element of the pannus, or that they are at least essential to its formation, completion, and maintenance. As a consequence, the course of these blood vessels must be permanently discontinued, if the pannus is to regress and disappear.

It has been noted that if the conjunctiva is circumcised at the limbus, a marked ischemia and consequent paleness and thinning of the pannus manifest

themselves. Both of these conditions persist if the conjunctiva is prevented from reattachment to its original position. When reattachment takes place, the ischemia is rarely followed by the disappearance of the pannus, but in most cases the blood vessels reappear in the cornea, the pannus reforms, and the previous condition relapses and persists. This disappointing result has not occurred in the cases in which the operation of conjunctival recession has been performed.

Observation of the different steps of the operation and its postoperative course emphasizes these points: (1) While performing the operation, we incise the conjunctiva around the cornea and at the same time sever the conjunctivo-corneal blood vessels, thus cutting the main blood and nutrition supply to the pannus. (2) By recessing and fixating the incised margin of the conjunctiva at some distance from the limbus, the reformation of the blood vessels in the cornea is rendered impossible. Since the blood vessels of the recessed conjunctiva become terminal-like, their previous terminations in the cornea become bloodless and in time atrophy. (3) This condition will be permanent, since the conjunctiva is permanently fixed to the new position.

It is worthy of remark that the conjunctiva, which the sutures hold far from the limbus at the time of the operation, will later, when the sutures are removed, be held in place by cicatricial bands formed along the wound channels. These bands unite the conjunctiva to the skin. Other cicatricial bands produce adhesions between the scleral surface of the conjunctiva and the underlying tissue, and there will be an all-around adherence of the incised margin of the conjunctiva to the sclera. In addition, the epithelium, coming from the borders of the wound, will cover the bare sclera shortly after the

operation and will prevent the conjunctiva from sliding along and becoming reattached to its original place.

The following advantages of the operation have been noted: (1) There is a permanent disappearance of the blood vessels from the cornea and consequent recovery from the pannus. (2) More or less clearing of the corneal opacities takes place. The cornea becomes more transparent and vision is improved. (3) The ulcerative relapses of the cornea, which affect recovery from the distressing symptoms of the trachoma, are ended. (4) Shrunken fornices are deepened. It should be pointed out here that in old trachoma the conjunctival fornices are eventually contracted and the upper one is exceedingly shallow if the mucotarsal resection has been performed. Evidently, if the cut margin of the conjunctiva is recessed for several millimeters and the entire membrane is displaced from the limbus towards the fornices, these fornices will become correspondingly deeper, and the relation between the eyeball and the eyelids will be improved.

SUMMARY

The vascularization of the cornea represents the only or the principal element of genesis and nutrition of the pannus. The permanent elimination of the blood vessels from the cornea is the best means to effect a cure, and the recession of the conjunctiva does this. The operation consists essentially in a permanent fixation of the circumcised margin of the limbal conjunctiva away from the cornea. By this means one can obtain permanent disappearance of the pannus, permanent improvement of the visual conditions, the end of corneal ulcerations, and a deepening of the fornices. These satisfactory results have been obtained in all operated cases. The social significance of these results is evident.

THE ORTHOPTIC TREATMENT OF THE VERTICAL MOTOR ANOMALIES*

MARY EVERIST KRAMER

Washington, D.C.

This paper is the result of the study and treatment of 67 cases of vertical squint, most of which were complicated by a lateral squint (table 1). Since there is still much to be learned regarding the functional origin and the neurologic background of vertical motor anomalies, the data obtained in this study is not conclusive.

The neurologic "question mark" of squint is a fascinating subject. We are only beginning to understand its importance in the motor disabilities¹ of the eyes. Further research and investigation of the neurologic factors involved are required. We should think of the neurophysiology and neuro-anatomy of the motor apparatus in addition to the physical and physiologic action of the extraocular muscles.

The findings in these 67 cases and the results of their treatment make clear the need for treating orthoptically the vertical motor anomalies whose origins are

functional as well as those in which there are lateral deviations.

Correct diagnosis is the first and most important step in initiating treatment.² No therapeutic measures should be instituted without ascertaining whether the cause is functional or anatomical, the exact nature of the existing condition, and the prognosis. The terms, right hypertropia or left hypertropia, do not constitute a diagnosis; neither do the terms paretic right or left hypertropia.

TYPES OF VERTICAL DEVIATIONS

There are five types of recognized vertical deviations:

1. *Concomitant*.³ An essential or mechanical vertical deviation in which the hypertropia or hyperphoria is the same in all the cardinal fields of gaze, with or without correction of the refractive error.

2. *Vertical deviations due to nuclear and infranuclear paresis*.⁴ A condition in which the vertical deviation is maximum in the field of the elevating or depressing action of the paretic muscle.

3. *Vertical deviations due to supranuclear paresis*.⁴ Those deviations, affecting the associated movements of the eyes,

TABLE 1
STUDY AND TREATMENT OF 67 CASES OF
VERTICAL SQUINT

	Number	Percent- age
Cases with only one type of hypertropia	43	64.5
Cases with more than one type of hypertropia	24	35.5
Cases complicated with a lateral tropia	56	83.5
Cases without horizontal tropia	11	16.5
Improved with orthoptic training	51	76.1
Unimproved with orthoptic training	12	17.9
DIAGNOSIS		
Concomitant hypertropia	4	6.0
Paretic hypertropia	16	24.0
Pseudo-paretic hyperphoria	2	3.0
Dissociated vertical divergence	23	34.0
Dissociated with paretic hypertropia	18	27.0
Dissociated with pseudo-paretic hypertropia	2	3.0
Intermittent squint in adolescents	3	
TREATMENT		
Postoperative treatment of vertical anomaly	8	13.0
Cases with no fusion before training	21	35.0
Cases treated surgically	15	16.0
Neurogenic cases	35	56.0
Amblyopia cases	32	53.0
Improvement without orthoptic training	4	6.5
Cases with vertical squint in which there was a complicating lateral squint where the treatment for vertical took precedence	26	43.0

which are caused by a weakness or paralysis originating above the motor nuclei in the pyramidal tracts or in the cortical centers. Since these types do not enter into the realm of orthoptics, they will not be discussed.

4. *Pseudoparetic hyperphoria.*⁵ This is a primary overfunction of one or both inferior obliques. This is believed to be due to absence of check ligaments.

5. *Vertical deviations of dissociated type.*⁶ These may be brought about by increased or abnormal innervations or by excitations from the centers of vertical divergence. These types are generally as-

sociated with other nervous factors unrelated to the eyes and are present in most cases of poor fusion as well as in cases of high degrees of esotropia and exotropia. They are usually present after surgical treatment of a vertically acting muscle.

TESTS FOR DIAGNOSIS

In our studies of the vertical motor anomalies, we have found that no one test is sufficient to make a diagnosis. One cannot make a final diagnosis on the findings of the prism and cover test alone. By the same token the diplopia tests cannot be used as the only basis for the diagnosis. The diplopia tests are valueless and misleading in cases of abnormal retinal correspondence, or when the innate directional value of retinal elements has been changed. Before any therapy is instituted, these preliminary measures are necessary:

1. A careful history should be taken.
2. A study of the general neurologic condition as well as the general physical and psychologic status of the patient should be made.
3. The results of the different tests—visual, refractive, the fixating eye, measurements in the cardinal fields of gaze as well as in the primary position—should be summarized. When a double hyperphoria is present (a right and left hyperphoria) these measurements should be made with each eye fixating.
4. There should be a careful study of the eye movements to determine whether (a) they are of the quick, regular movements in up and down excursions, such as are seen in the concomitant and in the recent or partially recovered paretic types of vertical deviations; (b) if they are of the over-shooting type, moving too far in the direction necessary for fixation, then making a quick movement in the opposite direction to accomplish foveal fixation; (this type of movement is often

noted after surgery on one or more of the extraocular muscles and sometimes in paresis of one or more of the extraocular muscles when the paresis is in a late stage and the contractures and overactions of the agonist and antagonist muscles are very excessive); or (c) if they are the slow, oscillating type of movement, sometimes accompanied by a wheel-like rotation, typical of the dissociated vertical deviations.

5. It should be determined whether or not the vertical squint is constant or intermittent.

6. The fusion status should be checked. If little or no fusion is present, a surgical procedure will result in little or no correction of the squint in almost every case. If fusion is present,⁷ the vertical, as well as the lateral fusion amplitudes, and the cyclovergences must be measured.

7. A correct diagnosis must be made.

To our knowledge, the troposcope is the only type of major amblyoscope that permits correction of high degrees of hypertropia, such as are found in the dissociated vertical disturbances. This is important because it is necessary to start at the angle of deviation and build up the fusional amplitudes from that point, just as one does in the lateral deviations. If there is a large degree of dissociated vertical deviation, it must be corrected at its maximum angle on the instrument. The vertical separation of the objects is gradually reduced. This teaches the patient to hold the images of the two eyes fused and is continued until he can easily fuse without any prismatic correction or without any vertical separation of the visual axes. A vertical prism ladder can also be used. These procedures teach the patient voluntary control of the vertical squint and give him an appreciation of diplopia at the vertical angle. This is especially true when dissociated vertical disturbances are present, because these patients do not appre-

ciate vertical diplopia unless taught to do so.

We have found that fusion training before and after surgery on a vertically acting muscle is a necessary therapeutic procedure. During the first week or 10 days after surgery, there are many abnormal innervations activating these muscles. These innervations may produce a high overcorrection one day; the next day there may be no deviation; then on a succeeding day, there may be a definite undercorrection, followed again by an overcorrection.

These variable findings make it most difficult to know how much benefit has been obtained surgically. Daily orthoptic observations and guarded fusion training during this period usually reduces or controls the abnormal innervations for as long as the fusion impulse takes precedence. Thus, in a very short time, the surgeon can objectively verify the amount of correction that has resulted from the surgical procedure and save the patient anxiety during those months following the surgery when abnormal innervations create such diverse amounts and types of deviation with accompanying diplopia.

A retention suture, which can be loosened or tightened from day to day, will enable the surgeon to get a very accurate result, if he can determine what amount of vertical deviation is innervational and what is mechanical or anatomic. If an orthoptic routine of fusional training and observation, including the vertical divergence fusional amplitudes, is instituted a few days after the operation, it will aid the surgeon in determining these factors.

CONCOMITANT HYPERTROPIA

In concomitant hypertropia, (hyperphoria or tropia) the amount of vertical deviation is approximately equal in the whole field of fixation, with or without glasses. This is corroborated by the prism

and cover tests and the diplopia tests which correspond in their measurements and are constant.

Often fusion training will relieve the patient of his symptoms, if the hyperopia is of low degree, but it will not correct the hyperopia. Teaching a patient to overcome a low degree of hyperphoria can be done as easily as teaching a patient to overcome an esophoria or an exophoria by increased fusional stimulus.

Fig. 1 (Kramer). *Case 1.* Divergent strabismus of the right eye, with divergence excess and convergence insufficiency. This was the result of an accommodative convergent squint which was overcorrected by glasses. The divergence excess was a probable etiologic factor in the accommodative convergent squint. The divergent squint was cured surgically. The concomitant hyperphoria was relieved orthoptically but not cured.

This is done by stimulating the innervations from the opposite center of vertical divergence; that is, if a patient has a right hyperphoria, the negative fusional vertical divergence is stimulated and strengthened. In other words, the negative vertical divergence is restricted in its fusional range to the same extent that the fusional range of the positive vertical divergence amplitude is enlarged. Stimulation of the vertical divergences is accomplished on the major amblyoscope and the vertical prism ladder; however, there is a limit of the fusional range beyond which it is impossible to enlarge. Usually the patient has to be trained to utilize the maximum innervation obtainable, thus enabling him to hold the visual axes level rather than

to permit one eye to deviate higher or lower than the other.

Attention should be given to the lateral fusional range. This also must be stimulated to its maximum, allowing the patient to utilize the increased fusional innervations to hold the visual axes in proper position for the maintenance of comfortable, single binocular vision. The degree of esophoria or exophoria will determine to what extent the vertical deviation can be overcome in a diverging or converging position. If an exophoria be present, binocular single vision will be more difficult to maintain in a converging position. In cases in which a strong impulse to fusion is present and in which high lateral amplitudes are easily attained, prism correction for constant wear is not required. However, neuropathic types and cases with weak fusion do not respond well to orthoptic treatment. Cases are selected upon this premise. In the higher degrees of hyperphorias and tropias, prism correction is indicated if surgery is not done.

CASE REPORT

R. E., a boy, aged five years, was first seen in Dr. Sheppard's clinic on October 30, 1939. The diagnosis was: convergent squint (O.D.) accommodative. After occlusion of the right eye for amblyopia, there was a divergent squint (O.D.) for distance and near. The right hyperphoria was concomitant (fig. 1). The report of the ophthalmologist who had seen this patient previously follows: "Patient was first seen March 24, 1939, with a right esotropia of 20 degrees with the following correction: O.D., +5.50D. sph. \ominus +1.00D. cyl. ax. 90°; O.S., +5.50D. sph. \ominus +0.75D. ayl. ax. 90°. Amblyopia right eye, with uncertain fixation, vision reduced to 20/100. The vision was 10/10 in the left eye. After occlusion of left eye for four weeks, he developed an am-

blyopia in this eye and an exotropia. Responded very well to orthoptics, vision became almost equal and eyes are straight with correction." This history was corroborated by the mother.

On October 30, 1939, the boy's vision was, 20/40, each eye, for distance and near, without correction. Because of his accommodative convergent squint, the vision, with both eyes straight, was only 20/100.

The Pcb was remote. There was an exotropia for near and distance with correction. Without correction he was seen to turn in the right eye fleetingly. He was wearing the correction prescribed by the ophthalmologist who had seen him previously. Without correction, with the prism and cover test, he measured orthophoria for distance and near; with correction, exotropia for distance, 10 to 18 diopters; exotropia for near, 6 diopters; with right hyperphoria, 2 to 4 diopters. His fusional amplitudes seemed normal. He left Washington with his parents and did not return until July 2, 1942. At that time his vision was: O.U., 20/70, without correction. He was wearing 1-diopter less hyperopic correction (+4.50D. sph: with cylinders) for each eye. On the synoptophore, with correction, he measured exotropia, 18 diopters; right hyperphoria, $2\frac{1}{2}$ diopters. He had no convergence fusional amplitude and a fusional divergence of 20 diopters. Under atropine he measured, prism and cover test, exotropia, 15 diopters for distance; exotropia, 15 diopters for near with right hyperphoria, 2 diopters. He was given the following prescription: O.U., +1.00D. sph. \ominus +2.50D. cyl. ax. 90° . He had a marked fusional instability with the reduced correction because of the right hyperphoria. He also had a constant diplopia.

On September 14, 1942, he was given the following correction: O.D., +2.50D.

cyl. ax. 90° , 3D. prism, base-down; O.S., +2.50D. cyl. ax. 90° .

Since the amblyopia in the right eye had returned, occlusion by covering the lens of the glasses with nail polish was prescribed. On November 24, 1942, a Jameson recession of 4 mm. was performed on the right lateral rectus. On December 4, 1942, the prism and cover test showed: Without correction, orthophoria for near and distance; right hyperphoria, $\frac{1}{2}$ diopter. With correction, orthophoria for distance; exophoria for near, 10 diopters; with left hyperphoria, 2 diopters. This latter finding indicated that the right hyperphoria was overcorrected by the 3-diopter prism, base down, in front of the right eye in his glasses. The Maddox-rod test showed: with correction, no lateral deviation, near and distance, right hyperphoria, 3 diopters. He was advised to go without glasses if he wished, and orthoptic training directed to the convergence was started.

This boy was very phlegmatic. The convergence never became good (30 diopters on the synoptophore), probably because the mental effort necessary to utilize the voluntary fusional impulses was inadequate. However, he could wear his astigmatic correction without prism correction of the right hyperphoria, could bar read well, could maintain an orthophoric position on the hand diploscope, and was perfectly comfortable when last seen on December 27, 1945. On the Worth 4-dot test he had fusion for both distance and near, without correction.

PARETIC HYPERTROPIA

The treatment of a paretic hypertropia is not orthoptic, but medical and surgical. Fusion training is often highly beneficial in recovered cases of pareses in that it aids in balancing the innervations to the antagonist and yoke muscles and makes for better coordination of the two

eyes in binocular vision. If the lateral fusional amplitudes are normal, orthoptic training should be directed to enlarging the vertical divergence amplitude that is deficient or restricted. After this the so-called "dissociation" exercises are given. This includes the diploscope, Remy separator, "hole in hand," and triple bar reading. In some cases of anisometropia or unequal vision, or in cases where there is a highly dominant eye, a red glass to be worn over the better or dominant eye (red kodaloid combined with a smoked glass) is given for reading and studying.

CASE REPORT

D.K., a boy, aged 12 years, was seen because of a paresis of the left inferior rectus. Vision was: O.D., 20/15, with a +0.50D. sph. \ominus +0.50D. cyl. ax. 160°; O.S., 20/15, with a +1.00D. sph. \ominus +0.25D. cyl. ax. 60°, 3½D. prism, base-down. Vision without correction was: O.D., 20/20-iii; O.S., 20/15.

When first seen on December 12, 1944, he had a head tilt, rotated to the left and depressed, and a left hypertropia of 54 diopters. Orthoptic training was directed to building up the positive fusional vertical divergence amplitude and overcoming the suppression of the right eye which existed without the correction. After three months of orthoptic training, he was perfectly comfortable and did not admit of any diplopia except when making an effort to obtain it in the primary position. The vision in the right eye improved to 20/15-i, without correction. He was within normal limits on the Howard Dahlman depth-perception test and had stereopsis on the orthoptic instruments. The amount of left hyperphoria had not diminished, but he was most happy that he did not have to wear glasses. Only surgery will correct the condition and since he wishes to become a pilot, surgery is indicated. We did not have an opportunity to ob-

serve him further as he moved elsewhere. However, his present ophthalmologist reported on October 13, 1946, that he is still doing fine.

PSEUDOPARETIC HYPERPHORIA

This type of hyperphoria is easily diagnosed even in a cursory examination. The adducted eye, being in the field of action of the overacting inferior oblique, deviates upward. There is no deficiency of the superior oblique of the same eye, its antagonist, nor of the superior rectus of the opposite eye, the agonist or yoke muscle, as verified by the diplopia tests and the rotations. If the hyperphoria is bilateral, it is present on dextroversion and levoversion. It is not present in the primary position except when combined with a parietic or dissociated type of vertical deviation.

No orthoptic treatment is indicated unless the patient is having symptoms, as there is no vertical deviation in the primary position. However, the majority of vertical phorias of pseudoparetic origin have a coëxisting lateral or vertical component. We find a fair percentage of accommodative convergent strabismus patients with a complicating pseudoparetic hyperphoria. With the correction and cure of the lateral squint, the pseudoparetic hyperphoria disappears. This may be explained by the fact that many accommodative squints have a very marked inshoot of the deviating eye, which, with the absence of check ligaments of the inferior oblique, give this muscle predominance in an eye that is excessively adducted over a period of time.

More frequently do we find pseudoparetic hyperphoria present in those cases of accommodative convergent strabismus with a small amount of hyperopia, with or without anisometropia, particularly in patients with a marked neurogenic background.

These cases should, perhaps, be placed in another classification rather than in the accommodative group. When tested monocularly, the accommodation is normal for the age of the patient. When tested binocularly, it is extremely subnormal, and the binocular vision for near may be as low as 20/800 on the Lebensohn chart. The initial treatment in these cases is the same as in a true accommodative convergent squint; that is, full correction of the refractive error, however small, with an additive of +3.00D. sph. bifocals for near. Relieving the accommodation with plus lenses seems to relieve the other innervational factor, which is the primary cause of the lateral squint and it may possibly relieve the pseudo-parietic hyperphoria. If we had an accurate and factual knowledge of the cortical centers and their interconnecting pathways, our empiric knowledge would be greatly enhanced and the treatment and cure of our patients more effective and rapid.

CASE REPORT

J. McP., a girl, aged six years, came to us on November 18, 1942, because of an alternating convergent squint, 25 percent mechanical and 75 percent accommodative. Heterochromia and pseudo-parietic hyperphoria were also present.

The history indicated that she had had a convergent squint of the left eye for the preceding $3\frac{1}{2}$ years. She was wearing a correction of +3.50D. sph. for each eye. The punctum proximum of accommodation was 9 cms., each eye, without correction, which was normal for her age and refractive error. Vision was: O.D., 20/30-i; O.S., 20/30+i, without correction. The prism and cover test showed: Accommodative esotropia 35 diopters for distance; esotropia for near, 40 diopters without correction. Not accommodating, under atropine, esotropia 3 diopters for

distance; esotropia for near, 20 diopters with correction and with a +3.00D. sph. added for the near measurement.

There was no hyperphoria in the primary position but an overaction of both inferior obliques when either eye was adducted. The following glasses were prescribed: O.D., +3.50D. sph. \subset +1.00D. cyl. ax. 70° ; O.S., +2.75D. sph. \subset +1.50D. cyl. ax. 85° .

Because of the intermittent squint for near and blurred vision with both eyes straight for near, the patient should have been given +3.00D. bifocals for near work. With glasses, O.U., eyes straight, she read 20/40 for distance and only 20/100 for near. Because of this, she did not do well when the orthoptic training was started in January, 1943, as it was too difficult for her to clear her vision even with the full distance correction, and the squinting for near vision continued. She was not too enthusiastic about the orthoptic training and the coöperation was not good, especially on the home training. On October 24, 1943, a Jameson recession of the left medial rectus (4 mm.) was done, with excellent result. Six days later she read, with glasses, O.U., straight, 20/20-ii, distance, and 20/25-ii, Lebensohn, for near. She had no alternation and maintained binocular single vision. Consequently the glasses were reduced to: O.D., +1.50D. sph. \subset +1.00D. cyl. ax. 70° ; O.S., +0.75D. sph. \subset +1.50D. cyl. ax. 85° .

Dissociation exercises were instituted with the continuation of amplitude training. Glasses were eliminated for outdoors. On February 4, 1944, she again had an intermittent convergent squint with glasses. Vision in both eyes, with correction, was 20/30 for distance and 20/200, Lebensohn chart, for near. With both eyes, without correction, the vision was 20/200, distance, and 20/400, Lebensohn, near. A +1.00D. stronger correction was

then prescribed. Several attempts were made to cure this case but all were unsuccessful. Finally on May 6, 1946, bifocal glasses were prescribed: O.D., +1.50D. sph. \ominus +1.00D. cyl. ax. 70°; O.S., +2.00D. sph. \ominus +1.25D. cyl. ax. 85°; with special +3.00D. cemented bifocals added. The accommodation was normal for her age, 7 cms. each eye, with correction. The fusional convergence was low, the fusional divergence normal. The vertical divergence fusional amplitudes were normal, 4 diopters each; the near point of convergence was normal, 5.5 cms. The squint was intermittent with and without glasses. Vision was: Without correction, 20/50 each eye; with correction, 20/15-ii each eye. O.U., without correction, 20/70-i, distance; 20/100, near; with correction, 20/40, distance; 20/65, near.

At that time the psychologic situation in the home had improved (antagonism between mother and child), and the child became much more coöperative. After the bifocals had been worn, there was a marked improvement in the general nervous condition and progress became steady.

When last seen on September 9, 1946, she was wearing the reduced distance correction for near work only and could do most of the dissociation exercises, with some difficulty in clearing the vision. The pseudoparetic hyperphoria had entirely disappeared. The near point of accommodation was 7.5 cms. each eye, without correction, and fusion for near and distance was present, without correction, on the Worth dot test. She could partially clear the orthophoric position on the diploscope and could clear transparencies on the Remy separator. The vision, O.U., eyes straight was: 20/20-iv for distance; 20/65 for near, without correction. With correction near vision O.U. was 20/30.

Pseudoparetic hyperphoria was not the

big factor in this case. However, the case does demonstrate that pseudoparetic hyperphoria in an accommodative convergent squint may be a more disturbing condition than is indicated and that it may, perhaps, have the same etiology if the refractive error is low, and the accommodation normal.

DISSOCIATED VERTICAL DIVERGENCE

This type is the most amenable of all the vertical motor anomalies to orthoptic treatment. It is easily recognized by its variability in type and amount, varying from a positive to a negative vertical divergence of greater or lesser degree. The position of gaze does not affect the degree; the fixating eye determines the type. If the right eye is fixating, there is a left hypertropia; if the left eye is fixating, there is a right hypertropia (providing the impulse to fusion cannot bring the deviating eye back to normal position). It is believed to originate in the cerebral centers for positive and negative vertical divergence in the region of the superior colliculi.⁸ Abnormal excitations bring about these varied deviations. The type of deviation depends upon the center innervated, and the amount upon the strength of the impulse or stimulus and upon the amount of illumination entering the eye. It is readily recognized by the slow, oscillating movement of the eye which has been covered or darkened with an optical wedge. With the red-glass test, the red image is lower no matter whether the red glass is held in front of the right eye or the left eye. Bizarre findings are characteristic of the diplopia tests. No matter how often these tests are made, the findings may differ widely on each test. With the increased darkening of one eye, the observer will note this eye making slow pendulous movements upward. As the darkening is decreased, the same slow, oscillating movements downward, often

accompanied by a wheel-like movement can be seen. The patient subjectively notes that the image seen by the eye which is darkened moves down farther and farther, indicating the upward deviation of the eye. As the darkening is gradually decreased, the image slowly moves up, indicating the downward movement of the eye, until the eye and image are horizontal with the opposite eye and image.

There is a general nervous instability present in most cases of dissociated vertical divergence, with or without a lateral component. Often there are abnormal physical conditions and psychologic maladjustments. Although of normal or even above normal intelligence, these patients frequently have a personality handicap which makes it difficult for them to get along with their own age group. However, they are either charming extroverts or interesting introverts.

CASE REPORT

S. McE., a boy, aged six years, was first seen on June 6, 1946, because of bilateral, dissociated vertical divergence and amblyopia ex anopsia of the left eye. He had had a resection of the left lateral rectus (10 mm.), and a recession of the left medial rectus (4 mm.) on March 9, 1945, by an Army surgeon, before he came to live in Washington. The convergent squint had been present since birth, and there was a family history of convergent squint. (The mother has a divergent squint of the right eye at this time, but states it was convergent all of her life until one year ago, when it began diverging, probably due to eccentric fixation and amaurosis.)

When the child was examined, he showed a trace of exophoria for near and distance. With the right eye fixating, there was a left hypertropia of 10 diopters for distance, 15 diopters for near. With the left eye fixating, the same amount of

right hypertropia was present both for distance and near. Vision was: R.E., 20/30; L.E., 20/100-i. The report from the Army surgeon stated that the right eye had been occluded for six months, and that vision in the left eye had improved from light perception to about 20/200. When examined under atropine, vision was: R.E., with a +2.25D. sph., 20/30. L.E., with a +2.50D. sph., 20/100. No glasses were prescribed. On the red-glass test, the red image was below with the red glass over either eye. There was a marked suppression of the left eye and constant occlusion was again instituted. He had peripheral fusion only, without amplitude, due to the deep-seated macular and paramacular suppression of the left eye.

Daily orthoptic exercises at the office for two weeks, with three weekly visits the following two weeks, were given. Training was directed to overcome the amblyopia and to improve the fusion. The wheel-like rotation was more marked in the right eye when treatment was begun, but improved markedly, with less marked improvement of this phenomenon in the left eye. After fusion developed with better fixation of the amblyopic eye, findings on the troposcope were: Subjective and objective setting, esophoria 4 diopters; *no hyperphoria*; fusional convergence 25 diopters; fusional divergence 9 diopters. With a 1-cm. target, he had a positive vertical divergence fusional amplitude of 30 diopters, recovery point at 22 diopters; and a negative vertical divergence fusional amplitude of 22 diopters, recovery point, 20 diopters. He had no cyclophoria on the horizontal lines. Incyclovergence measured 4 degrees as did the excyclovergence amplitude, which seemed subnormal in relation to the other fusional measurements.

His vision improved to 20/50-ii in the left eye. With the improved vision, his

fusion had improved, and consequently there was a lessening of the abnormal innervations for vertical divergence. Since he was only under treatment for one month, further progress cannot be reported.

GENERAL TREATMENT

The treatment should be general in that one should consider the person as a whole and all related factors, as well as the eyes, should be treated. If the general physical condition is below normal, immediate attention is given to this aspect. Attention is given to the environment, both at home and in school. There should be a minimum of psychologic disturbances and emotional stresses. General good health and plenty of outdoor exercise are prerequisites to a good prognosis for the eye condition. In cases in which the general nervous instability is marked, the orthoptic training should be guarded, as this may further strain an already overburdened nervous system.

Orthoptically, the treatment in these cases is essentially the establishment of good fusion and the correction of amblyopia, which is frequently present. Treatment is very similar to that of accommodative convergent squint. The patient can be taught voluntary control of the vertical deviation, just as the accommodative convergent squinter can control the lateral deviation. Dissociation training aids in teaching this control through mental effort.⁹ It is comparatively easy to build up good fusional amplitudes; in most cases they are normal or enlarged before any treatment is begun. However, if the orthoptic technician stops at this point, no progress is made because binocular instability is still present. A cure has been affected only after the dissociation exercises, both for near and distance, can be accomplished with comparative ease, and good binocular stability is established with

the disappearance of abnormal innervations. Some of the dissociation exercises are Dobson reading, bar reading, using a single, double, and triple bar successively, hand diploscope, reading the smallest legible print at 20 feet through a "hole in hand," Remy separator, using transparencies at first and then opaque objects, and finally reading.

In the beginning, voluntary fusion is taught without the aid of instrumentation, since it is easier to obtain without instruments. After the centers for willed fusional movements become stimulated by mental effort, the compulsion toward fusion becomes stronger with this reinforcement, and is cumulative with repeated effort. Gradually, the patient can accomplish this on a major amblyoscope, the Maddox wing, the diploscope, and the Remy separator. These are progressively more difficult in the order named. It is only when the patient finally succeeds in voluntarily maintaining fusion under these conditions that good results are obtained.

In cases having no fusion that are treated orthoptically for the establishment of fusion, the first sign of response to orthoptics is the appearance of a dissociated vertical divergence. As the suppression area is gradually reduced, and the double images gradually come closer to each other, and the paramacular area is reached, an *active antagonism to fusion* is demonstrated by an upward movement of the eye which is following a moving object as it is moved slowly toward the objective angle or the position where the foveas of the two eyes would fuse the images if fusion were present. This is subjectively noted by the patient when he observes that the image of the moving object goes under the image seen by the opposite eye, and when, as it approaches the opposite side of this image, he sees it come up to the same level with it. A careful observer will note the one eye moving

upwards and will then make a "searching" movement, gradually coming down and maintaining foveal fixation. This is done on the major amblyoscope, using 1-mm. to 5-mm. test objects in front of the "moving" eye and a larger dissimilar test object, preferably 2 cms. in size, in front of the opposite eye. As the suppression area is completely overcome and there is macular and foveal fusion, the dissociated vertical divergence movements disappear.

Surgery is contraindicated in cases of dissociated vertical divergence. If surgery is attempted in these cases, the results are usually as tragic as those of a surgically treated accommodative convergent squint. Both conditions are purely functional anomalies which have, possibly, the same or similar etiology.

Some ophthalmologists may feel, perhaps, that the question of diagnosis is outside the domain of the orthoptic tech-

nician. Since the diagnosis plays such an important part in the orthoptic therapeutic procedure of the vertical motor anomalies, this subject could not be discussed without mention of it. An orthoptic technician who cannot diagnose the type of vertical deviation present cannot treat it successfully.

I am deeply grateful to Dr. E. A. W. Sheppard, Louisa Wells Kramer, and the late Dr. William Thornwall Davis for their active interest and coöperation, which made research in this phase of orthoptics possible. It is my sincere hope that eventually others may interest themselves along these lines so that a broader knowledge will enable us to correct and cure the vertical motor anomalies with the same degree of success as the lateral motor disturbances.

DISCUSSION OF MISS KRAMER'S PAPER

ERNEST A. W. SHEPPARD, M.D.

Washington, D.C.

Miss Kramer has given briefly the characteristics of the different types of the vertical anomalies. While the final responsibility of the diagnosis of the type or types (there may be more than one type or more than one muscle involved either in one or both eyes) rests with the ophthalmologist, the interested orthoptic technician will try to see in how many

not be advised by an observant, experienced orthoptic technician. After all, she sees the patient for a much longer time than does he. There are few physicians who will not be advised by an observing, well-trained, and experienced nurse—why then should they not be advised by a similar orthoptic technician?

One test and one examination is not sufficient to make a diagnosis. This is particularly applicable to those cases which have strong fusion.

CASE REPORTS

CASE 1

History. P. S., a man (fig. 1), aged 32 years, was seen on August 13, 1938. His chief complaint was that the left eye deviated up and out (fig. 1).

Examination: Uncorrected vision, O.D., was 20/20 correctable to 20/15 with a +0.50D. cyl. ax. 60°. Uncorrected vision, O.S., was 20/30 correctable to 20/15-iii with a +1.00D. cyl. ax. 90°. The cover test showed: Exot. 20, LH 40 diopters; Xt'. 18, LH' 18 diopters, Pcb, 8 cms. The rotations showed paralysis of the right inferior oblique with overaction of the agonist, the left superior rectus, and of the antagonist, the right superior oblique. The fusion was poor but when he did fuse he did so at orthophoria.

Treatment. On October 6, 1938, a recession of the left superior rectus was performed. Tests made on the next day with the Maddox rod in front of the right eye showed: RH 1-3, RH' trace to LH' 4; Maddox rod in front of the left eye: LH 6-8, RH' 8. The cover test showed: LH 8, X 16 LH' 0, Xt' 25. The red-glass reading was: RH 5, RH' 8. Six days later the red glass in front of the right eye gave: LH 2½, LH' 2½.

Fig. 1 (Sheppard). *Case 1.* This shows a paralysis of the right inferior oblique. The eye with the paralyzed muscle is the fixating eye. A recession of the left superior rectus was performed. The good result is due to a correct differential diagnosis and to good fusion (pre-operative photographs).

cases her diagnosis agrees with that of the ophthalmologist. If they are not in accord, it is definitely to the benefit of the patient that an agreement—not a compromise—be reached. And let not the ophthalmologist stand upon his dignity and

The Maddox rod in front of the right eye showed: LH $2\frac{1}{2}$, LH' 4. The cover test showed: LH 6, LH' 8. The synoptophore reading was: LH 2.

On October 22, 1938, orthoptic training was instituted. Fusion was found to be poor with complete suppression of the macular area of the left eye. On November 22, 1938, no symptoms were presented. The Maddox-wing test gave: LH 3; the Maddox rod: LH 5, LH' 3; the synoptophore: LH $2\frac{1}{2}$; the cover test: LH 10, LH' 10, X 6, X' 6. There was no diplopia with the red-glass or Worth four-dot tests.

Eight years later, on January 21, 1946, this patient had an occurrence of diplopia while he was under nervous strain when at sea. There were no symptoms when he was rested. Readings on the Maddox tangent scale were: LH, 4 degrees of arc to 8 degrees, troposcope with fusion charts: LH 3D. On May 23, 1946, orthoptic training was instituted. Directed to third-grade fusion and binocular stability, it first attempted to break down the macular suppression of the left eye. On July 19th, the Maddox-rod test showed, LH 3-5; LH' 3-6D. The patient's symptoms had disappeared, and there was third-grade fusion and binocular stability.

Summary. 1. A case of paralysis of the right inferior oblique, in which the eye with the paralysed muscle was the fixating eye, is presented.

2. The yoke muscle, the left superior rectus, was recessed.

3. Subjective postoperative measurements were misleading; had they been depended upon and had the suture been tightened, the outcome would have been less satisfactory. This emphasizes the importance of the differentiation and the evaluation of subjective and objective tests.

4. Although the patient had very

marked suppression, orthoptic training developed a poor, unstable fusion into a strong fusion with binocular stability.

5. In civilian life, he was able to overcome LH 40D. and Xt 20, preoperatively; whereas, under the physical and nervous strain of Navy sea duty he was unable to overcome LH 10D. and had diplopia.

CASE 2

History. L. S., a girl (fig. 2), aged $2\frac{1}{2}$ years, was seen on October 11, 1935, be-

Fig. 2 (Sheppard). *Case 2.* This case presents convergent strabismus with right heterophoria. Eight operations were performed. Failure was due to an incomplete differential diagnosis and to abnormal retinal correspondence.

cause of a crossed right eye which had first been noticed when she was six months of age.

Examination showed Et 30D., Et' 35D. on the prism and cover test. The outward rotation of the right eye was restricted and there was marked up and in deviation of it; that is, "spasm of the right inferior oblique." Whether this overaction of the

right inferior oblique was secondary to paralysis of the right superior oblique or of the left superior rectus or both, or pseudoparetic, was never definitely determined. There was also a marked upward deviation of the left eye when adducted. No fusion was present.

Operations. 1. A Jameson recession of the right medial rectus was performed on April 28, 1936.

2. On January 19, 1937 a myectomy was done on the right inferior oblique.

Fig. 3 (Sheppard). *Case 3.* This woman, aged 52 years, had had a convergent strabismus since the age of seven years. A Jameson recession of the left medial rectus and a Worth advancement and resection of the left lateral rectus were performed. An old paralysis of the right inferior oblique was also present. The good result achieved in this case was due to a correct differential diagnosis and to good fusion (postoperative photograph).

3. A myectomy was done on the left inferior oblique on October 26, 1937.

4. A Reese resection was performed on the right lateral rectus on May 17, 1938.

5. On July 5, 1938, a Jameson recession was done on the left medial rectus.

6. On June 18, 1940, an advancement of the left inferior rectus was done.

7. An advancement of the left inferior rectus was done on July 30, 1940.

8. On the same date an advancement was performed on the right lateral rectus.

Examination on February 20, 1945, showed abnormal retinal correspondence both vertically and horizontally. The measurements were: Et 35, Et' 50, LH

30, LH' 25, with alternation and preference for fixation with the left eye.

Summary. 1. Surgery on the vertically acting muscles may well be deferred until one is absolutely sure of the diagnosis.

2. The differential diagnosis should be made, if possible, before any surgery is performed. The postoperative findings may not be characteristic, probably due to adhesions, scar tissue, or innervational factors.

3. In this case probably more than one type of deviation was present and both eyes were involved.

4. The unsatisfactory outcome was due to: (a) Not making a complete and correct diagnosis. (b) Operating before the diagnosis was made. (c) Abnormal retinal correspondence, both vertically and horizontally.

CASE 3

History. J. O'D., a woman (fig. 3), was first seen on June 16, 1923, when she was 30 years of age. She had an alternating convergent strabismus of each eye which had first been noted at the age of seven years. She had had no treatment other than glasses. Vision was 20/15 in each eye.

Examination. On April 8, 1937, cover-test findings were: Et 60, Et' 80D., with preference for fixation with the O.D.; on August 2, 1939, they were: Et 65, Et' 75; and on August 13, 1945, when the patient was 52 years of age, they were: Et 75D. Fusional amplitude on the synoptophore was from Et 70 to Et 95. There was normal retinal correspondence. A Jameson recession of the left medial rectus was done.

On April 20, 1945, the cover test showed: Et 40, Et' 40, LH 4-10. Rotations suggested an old right inferior oblique paralysis with overaction of the right superior oblique and the left superior rectus. Examination with the Mad-

dex tangent scale showed concomitant esotropia and concomitant LH.

Treatment. A Worth advancement and resection of the left lateral rectus was done on September 18, 1945. On September 25, the cover test showed: Xt 20, Xt' 25, Pcb remote. On October 6, 1945, the findings were: X 4, X' 4, LH 22, LH' 15, Pcb 15 cms. On October 15th, E 2, E' 2, LH 4, LH' 8, Pcb 10 cms. The following prescription was ordered: O.D., +100D. sph. = 20/15-i; O.S., +1.50D. sph. = 20/15-iii, Prism 3D., base down. Add +2.25D. sph. bifocals.

Orthoptic training was started on October 15, 1945. There was very marked suppression of the left eye, complete macular suppression. On March 4, 1946, the patient was comfortable without glasses for distance. The Worth-dot test showed fusion for near and distance; the cover-test findings were: E 2, E' 6, no hyperphoria; tests with the Maddox rod were: E 10, E' 15, LH 3-8, LH' 2-10; with the Maddox wing: E 13, LH 4; and with the troposcope: E 18, no LH, third-grade fusion.

On October 27, 1946, the troposcope showed: E 12, LH 2½; the Maddox wing: E 11, LH 4; the Maddox rod: E 6, E' 10-15, LH 2-7, LH' 4-7; the cover test: E 0, E' 6, +v.d. 3D., -v.d. 7D. The following correction was prescribed: O.D., +1.25D. sph. = 20/20+iii; O.S., +1.25D. sph. = 20/20-ii; add +2.00D. sph., bifocals. Glasses for near work only. The Worth-dot test showed fusion for near and distance, without correction.

Summary. 1. A high horizontal deviation may mask a low vertical deviation.

2. The patient had good fusion even after squinting for 45 years. The successful outcome was due to the strong fusion which was able to compensate for an LH of 0-7.

3. There was a marked psychologic improvement in the patient following the surgery. This undoubtedly had a favorable influence on the general nervous system which in turn favorably influenced the ocular nervous mechanism.

CONCLUSIONS

The vertical deviations present many more difficulties than the horizontal deviations because of:

1. The greater difficulties in diagnosis.
2. The lesser fusional amplitudes.
3. The greater difficulty in deciding upon what muscle to operate, what operation and how much.

For these and other reasons, orthoptic training in the vertical anomalies is essential. There is no material difference between orthoptic treatment of the vertical and the horizontal motor anomalies. The principles are the same; namely, differential diagnosis, correction of amblyopia and abnormal retinal correspondence, elimination of macular and foveal suppression, development and stimulation of fusion and fusional amplitudes and, lastly, good binocular stability for distance and near vision. The establishment of the last mentioned skill, good binocular stability, is the keynote for good results, orthoptically, in the vertical motor anomalies, more perhaps than in the horizontal motor anomalies.

THE PRESERVATION OF CORNEAL TISSUE BY FREEZING AND DEHYDRATION*

HERBERT M. KATZIN,[†] M.D.
New York

INTRODUCTION

One of the fundamental problems that confronted the Corneal Research Laboratory, when it was set up in conjunction with the Eye-Bank, was the study of methods to preserve the cornea. In the past, we were able to keep corneal tissue for a maximum period of three days. The corneas of adults were more easily preserved than those of infants or stillborn babies. There was also great individual variation in the ability of corneal tissue to withstand the autolytic processes that take place after removal. We attempted preservation of corneas in various hypertonic, isotonic, and hypotonic buffered physiologic solutions. We tried storing them as whole eyes or with the cornea detached. The most effective way to preserve them was found to be a moist chamber kept at 3° to 5°C. in which the eye was suspended above physiologic saline in such a manner that the cornea was never immersed in solution. The description of this chamber has been published elsewhere.¹

The publications by Weiss from the Department of Zoology of the University of Chicago came to our attention, and particularly the report on "The Transplantation of Frozen Dried Corneas in the Rat," by Weiss and Taylor.² If human cornea could be preserved in such a manner, it would be a great boon to the ophthalmic surgeon who could then have his graft material available at any time.

LITERATURE

The technique of fixation of tissues by drying while frozen, was first introduced by Altmann over 50 years ago, and this was described by Gersh.³ Further studies were made by Bensley and Gersh,⁴ Bensley and Hoerr,⁵ Hoerr,^{6,7} Simpson,⁸ and Taylor.⁹ These studies indicated that the histologic alterations in frozen tissues were due to formation of ice crystals which distorted the distribution of the protoplasm; that the more rapid the freezing process, the smaller the size of the ice crystals and the less the distortion. Further, that if the freezing had taken place at a very rapid rate and the ice removed by sublimation, the alteration in the histologic structure was minimal. Thus it was found, that the use of liquid nitrogen for freezing was the most satisfactory method; the tissues were immersed in practical isopentane that had previously been chilled with the liquid nitrogen. When the tissues were immersed directly in nitrogen, bubbles formed which acted as insulation and slowed up the process of freezing. Practical isopentane was used because it has a freezing point of about -200°C. Dehydration was performed by a diffusion vacuum pump which enabled the water vapor to sublime from the ice crystals and to be removed from the system by means of chemical dehydrators like phosphorous pentoxide. During the period of dehydration, the tissue was kept well below the freezing temperature of water.

The morphogenetic properties of frozen dried tissues were outlined in a paper presented by Weiss.¹⁰ Quick freezing and drying leave tissues in a more

* Under the auspices of the Ayer Foundation, in the Corneal Research Laboratory.

[†] Director of Research, The Eye-Bank for Sight Restoration, Inc., New York City.

normal condition than other preservative methods. These "devitalized" tissues remain relatively unmodified though their cells are dead. "This fact makes possible the study of the interrelationship between cells and matrix, by combining the 'devitalized' matrix of one tissue with living cells of another."

Weiss and Taylor¹¹ repaired injured peripheral nerves by grafts of frozen-dried nerve and proved they form excellent conductors for regenerating fibers. It was concluded through their experiments,¹² that by grafting frozen-dried nerves in cats and monkeys, full functional recovery may be obtained. A nerve gap of several centimeters could be bridged by the grafts of frozen-dried nerve, which had been stored for several months and rehydrated before use.

Frozen, dried, autogenous human skin grafting done by Webster¹³ proved successful in 80 percent of the cases. The best method, it was found, was to freeze the graft in CO₂ snow and butyl alcohol at -72°C. and then lyophilize in a vacuum which caused the graft to become shrunken, hard, and apparently dry.

Klinke¹⁴ demonstrated that mammalian cancers and embryonic normal tissue will survive freezing at very low temperatures. The tissues were dropped into liquid nitrogen or hydrogen and rapidly thawed in a few cc. of icy Tyrodes' solution, then cultured in nutritive media and tested with vital staining.

Experimentation using frozen cornea as donor tissue in corneal transplants was conducted by Smelser and Ozanics.¹⁵ Their studies showed that after eyes were frozen in isopentane, chilled with liquid nitrogen, and the cornea was used for grafting, the grafts became opaque in five days and remained so through 70 days (the period of observation). The grafts were easy to cut and were clear and normal in thickness until the cut edges came

in contact with physiologic saline solution, when they quickly became thick and edematous.

Transplantation of frozen-dried cornea in the rat was done by Weiss and Taylor² who reported satisfactory results. The grafted corneas in host eyes became incorporated by fusing circumferentially with the residual rim of the host cornea. They retained their laminated structure, and became resettled by the host cells, and remained transparent up to six weeks when the experiments terminated. These rat corneas had been placed in isopentane at -150°C.; evacuated at -40°C. for several days, then sealed in ampoules and stored. Before use, they were rehydrated in Ringer's Solution in vacuum, resuming normal consistency and appearance.

Detailed study was made of cultures of dried cornea by Filatov and Bazhenova^{16, 17} and Bazhenova,¹⁸ and it was concluded that corneas dried in a desiccator until the weight was constant, lost 76.3 percent of the original weight. The cornea preserved its ability to grow in tissue culture as well as its viability. The growth of dried cornea started later than that of fresh cornea which had been preserved in the ice box. Further studies of dried corneas were pursued in which the method of tissue cultures was used to show the preservation of viability in a cornea desiccated to the limit and then immediately moistened with Ringer's Solution. The conclusions were:

1. In prolonged preservation of dried cornea, 39.7-percent water should be retained for best results.

2. A cornea dried to the point where it loses 46 percent of its original weight or 60.3 percent of its water content, may be preserved at 2°C. for as long as 10 days and retain its viability.

3. Cornea dried at a low temperature may yield an extensive growth in tissue culture. The growth occurs chiefly in

epithelial cells, and begins only after 3 to 4 days.

Experimental transplantation of dried and frozen cornea on rabbits done by Filatov and Bazhenova,¹⁹ demonstrated the resistance of the cornea to chemical and bacterial processes. Dryness of the cornea and low temperatures are the two factors in this resistance. Corneas that have lost almost all their water content, may form a transparent implant if they are moistened soon after dried. Excellent results were obtained with corneas which had lost 15 to 20 percent of their original weight with subsequent conservation at 2 to 4°C. Freezing exerts a more deleterious effect on the cornea. Preserved at 3°C., the corneal transparency is retained, but the integrity deteriorates with further lowering of temperature. The isolated cornea gives better results than the cornea from a preserved eyeball.

Experimental preservation of cadaver eyes on ice in various preservatives was conducted by Petroysan.²⁰ Data from this experiment showed that eyes kept at 2° to 4°C. undergo changes which increase in intensity with the period of conservation. In the cornea, the epithelium became irregular, opaque, and edematous; opacity became pronounced on the seventh day when erosions appeared. The cornea remained transparent during the first eight days, but became opaque in 20 days. It remained transparent longest in a 1:2000 brilliant-green solution with the cornea upward. These changes in the epithelium have no effect on the fate of the corneal transplant; therefore, it was assumed that the corneal change in the early stages of conservation are not irremediable and do not prevent the cornea from returning to normal.

Skorodinska²¹ concluded that at low temperature the regeneration of corneal epithelium of eyes is possible.

COMMENT

The investigations concerning the preservation of the cornea conducted by the Russians were primarily done at ice-box temperatures and in a chemical desiccator. They also tried temperatures below 0°C., but reported failures. The freezing experiments of Smelser and Ozanics did not dehydrate the cornea, and were unsuccessful. It had been demonstrated, as noted above, that living cells could be frozen at very low temperatures and dehydrated and still preserve their viability. The question arose as to whether the cornea could retain its transparency and viability after such treatment.

Our own experiences with prolonged preservation of corneas at ice-box temperatures were not encouraging, therefore we hoped to be able to duplicate the work of Weiss and Taylor. Whether the graft is accepted by the host as a living tissue, or is replaced by the cells of the host, is still a subject of considerable controversy. If the donor cornea has to retain its viability, which is our belief, then the graft must be a living graft. Certainly if the host cornea will accept a living graft from another individual, the cornea is the only tissue in which this is possible.

APPARATUS

A freezing-dehydrating apparatus such as was described by Taylor²² was constructed. The manifold was made of glass, otherwise the apparatus was essentially the same (fig. 1). We found that the glass manifold made possible a more complete vacuum. The principle of the apparatus was to provide a constant stream of cold vapor from CO₂ ice, which was kept in the reservoir thermos jar (10 liters). The cold vapor poured down a copper tube into the smaller thermos jar (4 liters), and maintained a temperature in the latter vessel of -40°C. The tem-

Fig. 1 (Katzin). A frame of metal pipe supports the horizontal reservoir for CO_2 ice. Mounted above it is the McLeod gauge; in front of it is a glass manifold with the outlets as noted in the text. Between the manifold and the gauge is a separatory funnel containing calcium chloride. In the manifold there is a tray containing phosphorous pentoxide. Below the manifold there are three Flotsdorf-Mudd vials, the center one containing three frozen cornea discs. Behind these vials is the Hy-Vac pump. The cold-chamber thermos jar has been lowered to the floor and its supporting shelf swung to one side. An isopentane thermometer can be seen in front of the vials and behind the vials is the metal vane which acts as a thermoregulator for the cold chamber.

perature was regulated by a valve consisting of a metal vane controlled by a bi-metallic helical thermoregulator. The glass manifold provided with seven connecting tubes was mounted above the smaller thermos jar (the cold chamber). The outlets on the manifold were arranged as

follows: One was connected to a high vacuum, oil-diffusion pump; one to a McLeod mercury vacuum gauge; one was a 2-inch diameter, ground-glass stopper; and one was connected to a separatory funnel packed with calcium chloride and equipped with a valve to release the

vacuum; the remaining three extended into the cold chamber through its cover. The 2-inch ground-glass stopper was removable in order to place the tray containing the phosphorous pentoxide inside the manifold.

The frozen corneas were placed in rubber stoppered glass vials that attached to the three tubes which projected into the cold chamber. These vials are the type supplied for the Flotsdorf-Mudd lyophile apparatus.²³

Liquid nitrogen was transported in all-metal thermos bottles (of the type commercially available from the Stanley Manufacturing Company) and transferred when necessary by pyrex glass syphon tubes.

METHOD

Fresh donor eyes were obtained daily from rabbits which had been killed for the performance of the Aschheim-Zondek test. These eyes were enucleated and donor grafts removed by means of a 5-mm. automatic Green's trephine. It was found that three donor discs could be obtained from each eye. These discs were dropped into a test tube containing practical isopentane (Eastman Kodak Company). The isopentane was previously chilled by immersing the test tube in liquid nitrogen. A temperature of about -180°C . was obtained in this manner. The corneal discs froze immediately and were transferred to dry lyophile vials which were packed in a freezing mixture of CO_2 snow and acetone. As soon as the three frozen corneas had been transferred, the vial was placed in the cold chamber. Three such vials were evacuated at a time. Some of the grafts were frozen directly in liquid nitrogen instead of being immersed in isopentane, as will be noted below.

As soon as the vials were fixed to the

manifold connecting tubes, the system was evacuated and the vacuum maintained for a period varying between 4 and 11 days. Every two days the supply of CO_2 ice was replenished and the phosphorous pentoxide was removed and replaced. After the period of dehydration by evacuation, the vials were sealed in vacuo and placed in the ice box. The grafts were rehydrated in normal saline just prior to their use in cornea grafting.

The grafting operation was performed in routine fashion with a single preplaced, clover-shaped corneal stitch, and the rabbits were observed postoperatively for periods up to seven months.

In 11 instances, the grafts were dropped into chilled isopentane and in eight instances directly into liquid nitrogen prior to transferral to the freezing dehydrating apparatus. Eight grafts were dehydrated for four days, seven for seven days, three for nine days, and one for 11 days.

Fourteen of the donor grafts were transferred directly into the freezing liquid after having been freshly cut with a Green trephine. The remaining five were first washed with a 1:30-dilution of rabbit's serum.

In no instance was the cornea preserved for more than 48 hours after dehydration. When ready for use, the cornea grafts were removed from the sealed vial and dropped into normal saline solution one hour before the estimated time of transplantation. The rehydrated cornea was then used as the donor graft. The recipient eyes were normal.

RESULTS

It was found by trial that in one hour's time the frozen-dried graft dropped into saline would rehydrate and clear to a maximum degree. Longer periods would render the grafts too edematous. Of the

grafts that were used for transplantation, seven were translucent, six were clear in the center but opaque at the edges, two were opaque in the center but translucent at the edges, and four were completely opaque. When the graft was rehydrated, it was difficult in some instances to deter-

day; and one on the 21st day. Two rabbits died on the third day from extraneous causes.

CONCLUSIONS

Attempts to preserve rabbit corneas for transplantation by rapid freezing at the temperature of liquid nitrogen and de-

EXPERIMENTAL STUDIES IN RETROBULBAR NEURITIS*

P. J. LEINFELDER, M.D., AND W. A. ROBBIE, PH.D.

Iowa City, Iowa

The etiologic relationship of nutrition and intoxication to retrobulbar neuritis has long been a problem in ophthalmology and more recent studies have not particularly clarified the situation. This is not surprising since pellagra itself presents a number of etiologic problems, which, in part, have led some authors to classify their cases as simple pellagra, pellagra associated with alcoholism, and pellagra complicating other diseases. The occurrence of retrobulbar neuritis in the nutritional pellagra of past generations was relatively frequent, yet at the present time a change in this situation is recognized by Fine and Lachman,¹ for they state, "One wonders why the visual symptoms which were apparently so common in the pellagra of the last generation are so infrequent today." Calhoun² reviewed the literature in 1918 and reported 10 new cases of retrobulbar neuritis. Since that time, numerous reports of ocular complications in nutritional pellagra are found in the Russian literature, but only the five cases reported by Wagner and Weir³ in this country appear to be of primary nutritional etiology, and these did not occur in pellagra patients. It is noteworthy that at the present time among the numerous cases of nutritional pellagra seen in the southern part of the United States, few cases of retrobulbar neuritis are reported. In the North, most cases of pellagra are of the alcoholic type, and in these, and in the nonpellagra alcoholic, most cases of retrobulbar neuritis associated with nutritional disturb-

ances occur. The more recent American literature deals almost exclusively with the alcoholic variety of pellagra—Levine,⁴ Johnson,⁵ Fine and Lachman,¹ Carroll.⁶ In some of these patients, tobacco may have played a part, but, according to Carroll,⁷ "There has accumulated a considerable number of reports all tending to indicate . . . that so-called alcoholic polyneuritis is a manifestation of a deficiency disease and is not due to a direct neurotoxic effect of the alcohol."

A disturbing circumstance in this hypothesis is that many cases of retrobulbar neuritis of the tobacco and alcohol group show no manifestation of pellagra, and only a therapeutic response to thiamine hydrochloride indicates a relationship to vitamin B. Furthermore, retrobulbar neuritis occurs with great frequency in deficiency states in some parts of the world, and, although these patients are benefited by vitamin-B therapy, other factors of a toxic nature are recognized as contributing to the production of the syndrome. Moore,⁸ in 1937, reported the frequent occurrence of retrobulbar neuritis and optic atrophy in the numerous pellagrose natives of Nigeria. He quotes other observers from the Gold Coast, Jamaica, Solomon Islands, Barbados, and Malaya, who have observed a similar syndrome. Clark⁹ investigated the chemical nature of the diet of the Nigerians and determined that it was high in cyanide-bearing foodstuffs, and that the incidence of pellagra and optic neuritis was proportional to the cyanide content of the diet. Clark and Moore expressed the opinion that there is much clinically to support the presence of a toxic element plus a deficiency.

In 1943, McDermott, Webster, *et al.*,¹⁰

* From the Department of Ophthalmology, College of Medicine, State University of Iowa. Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

published the first report of the production of a nutritional degeneration of the optic nerves in experimental animals. They observed advanced optic-nerve degeneration in rats that had been on a B-complex deficient diet for 5½ to 12 weeks. With this information at hand and the possibility of a relationship between cyanide and the occurrence of retrobulbar neuritis, new methods of approaching the problem became evident. A series of experiments was planned in the hope that, by one or various methods, changes in the optic nerves of experimental animals could be studied. Because of the reports of McDermott and Webster, rats were used, and since Sprague-Dawley animals were available in our laboratory, these were used rather than the hybrid strain used in their experiments.

EXPERIMENTAL PROCEDURE

The basic synthetic diet for the rat experiments consisted of:

Cerelose	680 gms.
Casein (vitamin free)	180 gms.
Crisco	80 gms.
Salt mixture (Hubbell No. 351) ¹¹	40 gms.
Cod-liver oil	20 gms.

To this was added in crystalline* form for vitamin-B-complex supplement the following:

Thiamine hydrochloride	10.00 mg.
Riboflavin	20.00 mg.
Piridoxine hydrochloride	0.75 mg.
Calcium pantothenate	5.00 mg.
Nicotinic acid	50.00 mg.
Para-aminobenzoic acid	100.00 mg.
Inositol	100.00 mg.
Choline chloride	1.00 mg.

For exposure to cyanide the animals were placed in an air-tight cage through which air laden with hydrocyanic-acid gas in concentration of 3 gamma percent +1 was drawn.¹² This dosage of hydrocyanic-acid gas in air is one half the concentra-

tion that kills rats in from two to six hours. Appropriate diets were fed during the continuous exposure to cyanide.

Histologic material was removed from the experimental animals after killing them by breaking the necks. The eyes were fixed in Nissl's fixative and stained with cresyl violet for study of the ganglion cells of the retina. Pieces of the optic nerves and sciatic nerves were fixed in paraffin to be stained by Marchi's method for demonstration of early dissolution of the myelin sheaths of the nerves. Similar pieces of the nerves were fixed in Zenker's fluid for Held's myelin sheath stain,¹³ which demonstrates permanent destruction of the myelin sheath following atrophy of the axis cylinder.

EXPERIMENTS

1.—*Vitamin-B-complex deficient rats.* Groups of animals of equal weight, but varying in the different groups from 50 to 100 gm. were fed on the basic diet without vitamin-B supplement. In two weeks, evidence of deficiency consisted of poor appetite, failure to gain weight, and changes in the fur, but approximately four weeks had elapsed before arched back and stiff hind legs were apparent. There was slight loss in weight, and the animals looked poorly. These signs persisted and the animals died in from 4 to 10 weeks if allowed to go to termination. At various intervals, animals were killed and tissue taken for histologic study.

2.—*Thiamine deficiency.* Animals in groups of equal weight but varying between groups from 50 to 100 gm. were fed the basic diet plus all the B-complex supplement except thiamine hydrochloride. These animals followed the same course as the B-complex deficient animals.

2a.—*Thiamine deficiency plus exposure to hydrogen-cyanide gas.* This group of animals was placed on a thiamine-

* Crystalline vitamins were furnished by Merck & Company.

deficient diet and after a 2½-week depletion period was placed in the cyanide chamber. The deficient diet was continued and the course was similar to that of the animals in Group 2.

3.—*Riboflavin deficiency.* Animals of 40 to 50 gm. were placed on the basic diet plus the crystalline B supplement except for riboflavin. These animals did not increase in weight but remained alive for 4 to 6 months. Eyes, optic nerves, and sciatic nerves were taken when the deficiency was established.

4.—*Low protein and inadequate thiamine hydrochloride.* In this experiment the basic diet was modified by reducing the protein content from 18 percent to 9 percent. The thiamine supplement also was reduced to one half the usual amount. The experiment was continued for 21 weeks during which time, although the animals failed to gain weight, the skeleton continued to grow and, at the time of termination of the experiment, the osseous system was approximately that of a normal rat of the same age. Retina, optic nerves, and sciatic nerves were taken for histologic study.

4a.—*Low protein and inadequate thiamine hydrochloride plus exposure to hydrogen-cyanide gas.* A group of animals on the above diet was kept in the closed chamber and continuously exposed to hydrogen-cyanide gas. The duration of the experiment was 17 weeks.

5.—*Commercial diet plus hydrogen-cyanide gas.* Animals of approximately 200 gm. weight were exposed to hydrogen-cyanide gas in the gas chamber for a period of three months. Diet during this time was the commercial stock diet for small animals. These animals were allowed food at pleasure, and the amount eaten was recorded. There was no gain in weight, but the animals appeared healthy throughout the experiment.

5a.—*Limited commercial diet.* A group

of animals of approximately 200 gm. weight was fed on commercial diet for a period of three months. The food consumed was equal in amount to that consumed by the above Group 5. These animals also did not gain in weight, but they were much more active than the group exposed to cyanide.

6.—*Basic diet plus riboflavin and thiamine hydrochloride with hydrogen-cyanide exposure.* A group of 200-gm. rats was exposed to hydrogen cyanide and fed the basic diet to which was added four times the usual amount of riboflavin and thiamine hydrochloride. A record of the amount of food consumed was made. The experiment was continued for 12 weeks. The animals did not gain in weight but appeared healthy throughout the experiment.

6a.—*Basic diet plus riboflavin and thiamine hydrochloride.* These animals were of the same weight as those in Group 6 and were fed the same amount of diet that the cyanide group consumed. Except for greater activity, there was slight difference in the appearance of the two groups.

RESULTS

1.—*Vitamin-B complex deficient.* Although animals from this group had developed signs of extensive peripheral neuritis and were in a moribund state at the termination of the experiment, the optic nerves and retinas showed no evidence of involvement of the third visual neuron.

Sciatic nerve sections prepared by Marchi's method showed rather extensive acute degeneration of the myelin but evidence of permanent change was not observed in the Held preparations.

2.—*Thiamine deficiency.* Table 1 shows the histologic changes observed in tissues removed from these animals. In most instances, the degeneration of the myelin in

the sciatic nerve was advanced, as demonstrated by Marchi's technique, but was normal in the Held stain. Optic-nerve changes were minimal and consisted of only a few very fine droplets of black in most sections. No changes were observed in sections stained with the Held stain. Retinal ganglion cells appeared swollen but apparently this was not an irreversible

130 to 176 days on a deficient diet, the optic nerves were normal by Marchi and Held methods. Rather extensive disintegration of the myelin in the sciatic nerves was observed with the Marchi but the Held stains were normal. The retinal ganglion cells showed no significant changes.

4.—*Low protein and inadequate thia-*

M-8-9	5½ weeks	21 days	Normal	Normal	20%	Normal	Swelling

change since animals that had recovered from severe deficiency showed normal optic nerves and ganglion cells.

2a.—*Thiamine deficiency and cyanide.* These animals, in spite of the continuous exposure to an atmosphere of cyanide during the final three weeks of the experiment showed less change than did the previous group (table 2). Although the retinal ganglion cells were swollen, the optic nerves were normal with both Marchi and Held stains. Only in Marchi preparations of the sciatic nerve were changes observed, and these were not as great as those noted in Table 2.

3.—*Riboflavin deficiency.* After from

mine hydrochloride. As shown in Table 3, sciatic-nerve myelin degeneration was noted in Marchi's preparations in varying amounts, and it occurred as early as 2½ weeks. Held stain of the myelin sheaths failed to show any evidence of permanent degeneration, and after a recovery period, the Marchi stains were normal. The optic nerves showed only a small amount of myelin degeneration by the Marchi method and no changes were seen in the Held stain. The retina was normal.

4a.—*Low protein, inadequate thiamine hydrochloride and cyanide.* In this series of animals, Table 4, the degenerative phenomena in both the optic and sciatic

nerves were considerably greater than in the control, Group 4. Myelin disintegration was more extensive with the Marchi stain, but here, too, evidence of irreversible degeneration was not obtained by Held stain. After a recovery period of

nerve (table 5). The retinal ganglion cells were normal and the Held stains were normal.

5a.—*Limited commercial diet.* After three months on the same diet as Group 5, the optic nerves showed somewhat

nerves, and the ganglion cells showed swollen nuclei.

DISCUSSION

In none of the experiments was significant degeneration in the optic nerves observed. This is particularly interesting in that the groups on vitamin-B-complex

deficiency and those on thiamine deficiency were reduced to extreme degrees of malnutrition and were at the point of death at the time of the removal of tissue for examination. Furthermore, these experiments fail to confirm the work of McDermott, Webster, *et al.*, who had previously reported the occurrence of degeneration in the optic nerves of rats fed on a B-complex deficient diet. One regrets that these observers did not report the condition of the ganglion cells of the retina, for this information would have contributed greatly to the value of their experiments.

In the event that there is irreversible degeneration in the optic nerves, the ganglion cells undergo chromatolysis and eventually disappear. When the changes in the nerve are reversible there is usually clearly defined evidence of the injury to the nerve by the reaction in the ganglion cell. This consists of swelling of the nucleus, peripheral clumping of the Nissl substance, and vacuolation of the nucleus which is pushed to the side of the cell. Cells so affected usually return to normal when the disease process in the nerve has healed, although a few ganglion cells may go on to complete dissolution. Unfortunately, in our studies, conclusive evidence of injury to the ganglion cells was not obtained. In all instances these cells were closely studied by the Nissl technique, and in many instances swelling of the nuclei and fragmentation of the cells were observed. However, this observation at times was made on ganglion cells from normal retinas. It could be assumed that in those cases in which there was injury to the nerve as demonstrated by the Marchi stain that there was some chromatolysis of the ganglion cells, but this assumption is dangerous in that chromatolysis should be a substantiation of the Marchi method. Had our experiments shown decisive degeneration in the optic

nerves, chromatolysis in the ganglion cells would be necessary to prove the validity of the optic-nerve damage.

Swank¹⁴ has observed that starvation produces myelin-sheath degeneration, but that only when there is concurrent degeneration in the axis cylinder (and, *per se*, chromatolysis in the ganglion cells) can a diagnosis of the thiamine deficiency be made. In some of our animals, starvation conditions were approached (tables 4 and 5). In the group of animals fed on restricted quantity of commercial diet, slight degeneration was observed in the myelin sheaths of both the optic and sciatic nerves, yet no attempt had been made to deplete the diet of any of the essential elements. The animals received only a sufficient amount of food to maintain their weight. The rats shown in Table 5 also received only sufficient food to maintain their weight, but there was a deficiency of all the members of vitamin-B complex except thiamine hydrochloride and riboflavin. These were given in four times the required amount, and in this experiment the degenerative changes in the sciatic nerve myelin sheaths were extensive, but the optic nerves were normal. The amount of degeneration seems comparable to that which occurs with thiamine deficiency alone. Since an absence of thiamine in the diet is followed by a loss of appetite, it becomes difficult to evaluate the relative effect of starvation and the deprivation of vitamin B₁ on the degenerative phenomena that we have observed.

The cyanide experiments were devised in order to attempt to duplicate the dietary circumstances of the Nigerian natives. In large doses, cyanide produces nerve degeneration and areas of necrosis in the brain,¹⁵ and in pigeons¹⁶ its effect has been compared with that of thiamine deficiency. Experiments had previously not been made with low sublethal con-

centrations of cyanide acting continuously over a long period of time, but we succeeded in maintaining a concentration of 3 gamma percent (± 1 gamma) in air for an indefinite period of time. Table 4 shows the results of hydrogen cyanide in this concentration on the optic and sciatic nerves of rats after three months' exposure. Some slight degeneration of the myelin of the optic nerves was present, but more definite change was noted in the sciatic nerves. This amount of change was not great, and the amount was not consistent from one animal to another. It was observed that exposure to this concentration of cyanide caused loss of appetite and failure of the animals to gain in weight. When thiamine is removed from the diet and cyanide administered in the air, the amount of degeneration is little different from the control animals on thiamine deficiency alone. This experiment was of only $5\frac{1}{2}$ weeks' duration, so conclusive evidence of comparative effects of cyanide were not available. To allow the animals to survive a longer period of exposure, the diet was changed to include one half the required amount of thiamine, but in order to intensify the effects of the cyanide, if possible, the protein content of the diet was reduced to nine percent instead of the usual 18 percent. These animals survived four months and showed variable amounts of change in the optic and sciatic nerves. Apparently there is slightly more degeneration in the cyanide-exposed animals than in the "control

group" with dietary deficiencies alone.

In order to determine the effects of thiamine and riboflavin as factors in preventing degeneration, another group of animals was used in which vitamin-B-complex factors other than riboflavin and thiamine were deficient. The thiamine and riboflavin content was increased to four times normal but, in spite of this, extensive degeneration occurred in the myelin of the sciatic nerves of the animals exposed to cyanide. These animals did not eat well and failed to gain weight during the 83-day experimental period, but there were no external evidences of vitamin deficiency. The experiment was planned for a longer period of time but was terminated because of mechanical difficulties with the cyanide chamber.

A method for producing uniform and extensive degeneration in the optic nerves and retinal ganglion cells of rats has as yet not been found. Part of our difficulty may be due to short duration of the experiments, and present work is directed toward correcting this. Long-time exposures of the animals to a relative deficiency rather than a complete lack of some or of all members of the B complex may yield better results. Further experiments with limitations of protein, especially the sulfur-bearing ones, may limit the detoxifying powers of the animals, and thereby increase the effect of the cyanide. The age of the rats has not been a factor in degenerative phenomena thus far, but further study of this must be made.

NONPERFORATING OCULAR INJURIES IN SOLDIERS*

BENJAMIN RONES, M.D., AND HELENOR CAMPBELL WILDER
Washington, D.C.

Approximately 4,000 eyes enucleated in army hospitals between Pearl Harbor and V-J Day have been received at the Army Institute of Pathology. This material is being subjected to pathologic study in an effort to obtain additional information regarding the reaction of the ocular tissues to trauma. The great majority of injuries were perforating wounds with or without retention of foreign bodies. These will be considered in a subsequent paper. This report deals only with those injuries which did not include penetration of the eyeball. The number of soldiers incurring ocular wounds of this description was 104; 47 during combat or training; 57 before entering the service.

The interval between injury incurred during combat or training and enucleation varied from less than one day to 2½ years. These cases have been studied by subdividing them on the basis of time elapsing between injury and enucleation—less than one day, one day to two weeks, two weeks to three months, and three months to 2½ years.

EYES ILLUSTRATING IMMEDIATE CHANGES

Four eyes enucleated on the day of injury illustrate the changes which were immediate.

CASE 1. A.I.P. ACCESSION 80348

The patient was unconscious and was bleeding from the nose and right eye when brought to the hospital immediately following an airplane crash. He was found to have a penetrating wound through the right orbit, which had caused fracture of the orbit, laceration of the cerebrum, and cerebral hemorrhage.

Pathologic observations. Hemorrhagic and serous exudate with a high polymorphonuclear leukocyte content was present in the orbital tissues attached posteriorly to the globe. There was a little hemorrhage into the anterior chamber; red blood cells clung to the posterior surface of the iris and to the ciliary processes. On one side there was hemorrhagic detachment of the choroid. Degenerative changes were beginning to take place in the lens.

CASE 2. A.I.P. ACCESSION 88565

A 50-caliber cartridge exploded in the patient's hand, injuring the eye.

*From the Army Institute of Pathology, Washington, D.C. Read before the American Academy of Ophthalmology and Otolaryngology, October 17, 1946.

Pathologic observations. Massive intraocular hemorrhage had occurred in the shallow anterior chamber, in Schlemm's canal, beneath the detached ciliary body, choroid, and retina, and in the vitreous chamber. A metallic foreign body was found in the adherent orbital tissues.

CASE 3. A.I.P. ACCESSION 91571

The patient was struck by an automobile, receiving a compound comminuted

Fig. 1 (Rones and Wilder). Rupture of the meshwork of the anterior chamber angle. Hemorrhage in the canal of Schlemm. $\times 240$. A.I.P. Negative No. 90121.

fracture of the right side of the skull, and an orbital injury. The eyeball was dislocated external to the lids, and the optic nerve appeared to be ruptured.

Pathologic observations. On one side hemorrhage engorged Schlemm's canal (fig. 1). Rupture of the filtration angle may have resulted from the concussion, but the coloboma of the iris seemed to be an artefact. Hemorrhage had occurred in the ciliary body, and there was hemorrhagic detachment of the choroid. Hemorrhage, with a rather high polymorphonuclear leukocyte content, was present in the anterior and vitreous chambers. The ciliary processes were edematous. The nerve head was covered by hemorrhage.

Beginning degenerative changes were apparent in the cortical lens fibers.

CASE 4. A.I.P. ACCESSION 123954

The patient was in a vehicle wreck, and the right eye was gouged out.

Pathologic observations. Recent hemorrhage was observed in the angle of the anterior chamber, in the posterior chamber, and around the ciliary processes. There were small subretinal hemorrhages near the disc. The optic nerve was severed traumatically.

The dominant finding in these four eyes enucleated the day on which the injury was incurred was fresh hemorrhage. Blood was found in all the ocular interspaces and throughout all intraocular structures. The mechanical effects of the blow and the amount of blood were factors which determined the variations in the ocular architecture. It is noteworthy that in two of these cases incipient cataract was identified less than 24 hours following injury.

EYES REMOVED WITHIN TWO WEEKS

Eight eyes removed within two weeks of injury illustrate the changes which took place relatively soon after trauma.

CASE 5. A.I.P. ACCESSION 104621

The patient, who was in a truck accident, had severe proptosis with apparent evulsion of the optic nerve.

Pathologic observations. The optic nerve appeared to have been pulled out. There was dense thickening of the sclera. Massive hemorrhage was both intraocular and orbital, with hemorrhagic detachment of the ciliary body, choroid, and retina. The lens was cataractous. There was purulent panophthalmitis and orbital cellulitis (fig. 2).

CASE 6. A.I.P. ACCESSION 101534

The patient was struck in the eye with

a baseball, which caused hemorrhage into the anterior chamber. Two days later a massive intraocular hemorrhage produced secondary glaucoma. Paracentesis was performed five days after injury.

Pathologic observations. Polymorphonuclear leukocytes infiltrated the corneal stroma. The iris was hemorrhagic, necrotic, and infiltrated by purulent exudate, and on one side was torn away from the ciliary body. Hemorrhage from the filtration angle filled the anterior cham-

ber, and was evident beneath the retina at the ora serrata, in the anterior vitreous, and in the cupped optic disc.

CASE 8. A.I.P. ACCESSION 102835

Injury to the eye from an exploding cartridge caused hemorrhage into the an-

Fig. 3 (Rones and Wilder). Rupture of the filtration angle. Hemorrhage in the anterior and posterior chambers. $\times 70$. A.I.P. Negative No. 90132.

terior chamber with resulting secondary glaucoma.

Pathologic observations. The filtration angle was ruptured. Hemorrhage was present in the anterior and posterior chambers (fig. 3).

CASE 9. A.I.P. ACCESSION 116154

Shell fragments had entered the patient's left cheek and cut the right optic nerve.

Pathologic observations. There was a ring abscess of the cornea. Purulent exudate occupied the anterior and posterior chambers and the filtration angle, and also infiltrated the ciliary epithelium. There were broken posterior synechiae. The ciliary processes were partially hyalinized. On one side the retina was torn and extensive subchoroidal and subretinal hemorrhages were present. The optic nerve appeared edematous and degenerated, and purulent exudate infiltrated the trabeculae and nerve sheaths.

CASE 10. A.I.P. ACCESSION 131220

A mine explosion in battle caused a

Fig. 2. (Rones and Wilder). Evulsion of the optic nerve. Rupture of the filtration angle. Massive subchoroidal hemorrhage. A.I.P. Negative No. 90178.

ber, and was evident beneath the retina at the ora serrata, in the anterior vitreous, and in the cupped optic disc.

CASE 7. A.I.P. ACCESSION 112891

The patient was struck in the eye by a hard object; hemorrhage and secondary glaucoma resulted. Posterior sclerotomy and iridectomy were performed, but the iridocyclitis and secondary glaucoma persisted.

Pathologic observations. Organized hemorrhage was present in the anterior chamber, occluding the pupillary space, and in the vitreous. Chronic iridocyclitis was evident, and iris tissue was incar-

penetrating wound of the left cheek and contusion of the left eye.

Pathologic observations. There was massive intraocular hemorrhage. The cataractous lens was dislocated into the posterior vitreous; the retina was detached; and gliosis had occurred. The pigment epithelium of the ciliary processes was proliferated, with wide-spread scattering of pigment cells. Organization of the vitreous hemorrhage had begun.

CASE 11. A.I.P. ACCESSION 115207

The patient was struck by an automobile and incurred a head injury which resulted in death.

Pathologic observations. The retina was edematous and folded in the macular region. Small hemorrhages were present in the inner nuclear layer of the retina. Although there was slight edema of the optic nerve head, physiologic cupping was still present.

CASE 12. A.I.P. ACCESSION 136147

The patient was struck by a mortar shell which caused a severe contusion of the left eye with iridodialysis, traumatic cataract, and intraocular hemorrhage.

Pathologic observations. There was massive hemorrhage into the anterior chamber. On one side the iris was torn away from the ciliary body, and beneath this the lens capsule had been ruptured at the equator. The lens was cataractous. Extensive posterior synechiae were present. The epithelium of the iris and ciliary body was proliferated; the ciliary body hemorrhagic and infiltrated with chronic inflammatory cells. There was a massive vitreous hemorrhage. The lamina cribrosa was markedly depressed.

In the eight eyes described, enough time had elapsed after the injury for beginning organization of the intraocular hemorrhages to have become apparent. Inflammation, present in five eyes, was

purulent in three. Secondary glaucoma had resulted from massive intraocular hemorrhage in four eyes.

TWO WEEKS TO THREE MONTHS

Fifteen eyes enucleated between two weeks and three months following injury were also examined, and in them the organization of hemorrhage was more advanced, the incidence of chronic inflammation had increased, and early atrophic changes were seen.

CASE 13. A.I.P. ACCESSION 116524

The patient was hit in the eye by a fragment from an exploding booby trap. Ciliary injection and hypotony appeared. The eye was enucleated one month after injury.

Pathologic observations. The pupillary margin of the iris on the temporal side was ruptured, and posterior synechiae and a pupillary membrane had developed. There was phagocytized hemosiderin in the anterior chamber and in the residuum of hemorrhage in the vitreous. There was hemorrhagic and serous separation of the retina with edema of the macula.

CASE 14. A.I.P. ACCESSION 118213

Fragments from an exploding booby trap struck the eye, causing iridodialysis. Recurrent intraocular hemorrhages produced secondary glaucoma. Paracentesis

Fig. 4 (Rones and Wilder). Massive hemorrhage in the anterior chamber. $\times 12$. A.I.P. Negative No. 90124.

was performed. The eye was enucleated six weeks after injury.

Pathologic observations. Traumatic iridodialysis was present, together with hemorrhages and atrophy of the iris. There were anterior and posterior synechiae, and a massive hemorrhage in the anterior chamber (fig. 4). The lens showed an anterior cortical cataract. The macula was edematous, and secondary

terior synechiae, atrophy of the iris, disorganization of the iris pigment epithelium, and scar tissue on the anterior

Fig. 5 (Rones and Wilder). Early depression of the lamina cribrosa. $\times 40$. A.I.P. Negative No. 90133.

glaucoma was manifested by the depressed lamina cribrosa (fig. 5).

CASE 15. A.I.P. ACCESSION 81675

Flying fragments of the skull of another soldier struck the patient's right eye, causing severe contusion with intraocular hemorrhage and traumatic cataract. Active panophthalmitis developed two weeks after injury and did not respond to treatment. The eye was enucleated 34 days after injury.

Pathologic observations. Blood pigment was present in the interlamellar spaces of the cornea. Hemorrhagic and serous exudate containing pigment-laden phagocytes filled the anterior chamber. On the nasal side, the iris was almost completely replaced by organizing hemorrhagic and inflammatory exudate which formed an adhesion between the cornea and the lens. On the other side were peripheral an-

Fig. 6 (Rones and Wilder). Organizing hemorrhage in the anterior chamber, resulting from traumatic iridodialysis. Extensive anterior and posterior synechiae. Atrophy of the iris and ciliary body. Cataract. $\times 8$. A.I.P. Negative No. 90149.

surface of the iris. The lens had undergone degenerative change (fig. 6). The ciliary body was atrophic, and on the nasal side its processes were pulled forward by organizing hemorrhage in the anterior vitreous. Chronic inflammatory cells infiltrated the uveal tract. Lymphocytic periphlebitis was evident in the retina with edema and folding in the macular region. Secondary glaucoma was evidenced by the depressed nerve head and lamina cribrosa.

CASE 16. A.I.P. ACCESSION 112157

The eye was struck by a stream of water from a fire hose, with resulting intraocular hemorrhage, dislocated lens, and lacerated iris. Paracentesis was performed. The eye was enucleated 25 days after injury.

Pathologic observations. Organizing hemorrhage was present in the anterior chamber. The cornea was blood stained; the iris lacerated; the retina partially detached, and there was hemorrhagic detachment of the choroid. The lens was cataractous. Subacute keratitis and iridocyclitis were observed.

CASE 17. A.I.P. ACCESSION 122874

Contusion caused severe hemorrhage into the anterior chamber, and secondary glaucoma. The eye was blind and painful. An attempt was made to extract a traumatic cataract. The eye was enucleated six weeks after injury.

Pathologic observations. The cornea and scar of the operative wound at the limbus were infiltrated with chronic inflammatory cells. Organizing hemorrhage filled the anterior chamber. Remnants of the lens capsule and cortex were visible. A massive abscess and hemorrhage filled the vitreous. A large subchoroidal hemorrhage was present, and the retina was detached.

CASE 18. A.I.P. ACCESSION 86403

The eye was injured by a gun-powder explosion, and enucleated seven weeks later.

Pathologic observations. Schlemm's canal was filled with serous exudate and surrounded by dense lymphocytic infiltration. Chronic inflammatory cells and polymorphonuclear leukocytes clung to the posterior corneal surface, to the anterior surface of the iris, and to the zonular fibers. The iris was edematous and infiltrated by plasma cells and lymphocytes, as were also the ciliary body, the inner layers of the retina, and the nerve head. The ciliary body and the peripheral choroid were stretched by the traction of plastic inflammatory exudate in the anterior vitreous.

CASE 19. A.I.P. ACCESSION 118751

A shell fragment penetrated the orbit. The eyeball was not perforated, but the globe became shrunken and painful. The eye was enucleated 18 days after injury.

Pathologic observations. The lens was cataractous and dislocated into the pos-

terior vitreous. The iris was ruptured. There was organizing massive intraocular hemorrhage. The retina was detached and disorganized.

CASE 20. A.I.P. ACCESSION 105515

Injury to the eye resulted from a powder explosion. The eye was enucleated two months later.

Pathologic observations. Epidermalization of corneal epithelium had taken place over the scarred and vascularized substantia. Pigment granules were seen in the spaces of Fontana. The iris was edematous. The ciliary body was atrophic and sparsely infiltrated by chronic inflammatory cells. Its processes were partially hyalinized. There was microcystic degeneration of the outer plexiform layer of the retina, as well as serous exudates in the outer plexiform and nerve-fiber layers. Degenerative changes were present in the anterior cortical fibers of the lens.

CASE 21. A.I.P. ACCESSION 101532

A blow caused hemorrhage and secondary glaucoma in an eye which had been defective since birth. Calcareous deposits were seen in the cornea; the lens was opaque, and annular posterior synechiae were present. The eye was enucleated two months after injury.

Pathologic observations. The cornea showed pannus degenerativus with calcareous deposits and vascularization. Inflammatory tissue and organizing hemorrhage formed a membrane which covered the anterior surface of the iris, occluded the pupillary space, and incarcerated the degenerated remains of the lens. The ciliary processes adhered to the posterior surface of the iris. Posteriorly there was ossification of the choroid. Lymphocytes and plasma cells infiltrated the uveal tract. The retina was detached, and the subret-

inal space was filled with serous exudate containing hemorrhage, cholesterol slits, and phagocytic wandering cells. The retina, which had undergone gliosis and microcystic degeneration, contained serous exudate and laminated drusen, and obliterative changes had taken place in some of the retinal vessels.

CASE 22. A.I.P. ACCESSION 105522

The patient was struck in the eye by a piece of wood, which caused laceration of the iris and retinal detachment. The eye was enucleated two months after the injury.

Pathologic observations. On one side, the iris was torn away from the ciliary body and was hemorrhagic and partially necrotic. Hemorrhage filled the coloboma and extended into the posterior and vitreous chambers. On the opposite side, strands of organizing hemorrhage and pigment-laden cells were present in the filtration angle. Degenerative changes had occurred in the cortical lens fibers. Hemorrhage had caused detachment of the retina, and there was massive subretinal hemorrhage in the macular region.

CASE 23. A.I.P. ACCESSION 146081

The patient was struck by a baseball on the left side of the forehead. At first no injury to the left eye was apparent, but two days later a large hemorrhage occurred in the anterior chamber. An intractable secondary glaucoma followed, and repeated paracentesis of the anterior chamber did not relieve the pain. The eye was enucleated three weeks after injury.

Pathologic observations. The massive hemorrhage in the anterior chamber contained considerable scattered pigment from the epithelial layer of the iris. On one side, the iris and filtration angle were ruptured, and the iris was necrotic. The pigment epithelial layer of the retina showed considerable hyperplasia.

CASE 24. A.I.P. ACCESSION 131247

A shell fragment penetrated the lid and the floor of the orbit, causing iridodialysis and massive vitreous hemorrhage. The eye was enucleated 15 days after injury.

Pathologic observations. A traumatic coloboma with organizing hemorrhage occupied the defect. Extensive rupture and detachment of the choroid and retina were present. There were large hemorrhages in the anterior and vitreous chambers, and in the subretinal and subchoroidal spaces.

CASE 25. A.I.P. ACCESSION 140195

Fragments from an exploding booby trap struck the eye and caused severe intraocular hemorrhage, rapid swelling of the lens and secondary glaucoma. One month after injury the lens was removed. The eye was enucleated seven weeks after injury.

Pathologic observations. There was a large operative scar in the cornea to which there were extensive adhesions of the iris, and of lens fragments and capsule. Inflammatory scar tissue occluded the pupillary space. A large organizing hemorrhage was present in the anterior vitreous, and there was extensive serous detachment of the retina. Subacute iridocyclitis was complicated by eosinophilia.

CASE 26. A.I.P. ACCESSION 132983

Injury to the eye in battle caused severe vitreous hemorrhage and complete detachment of the retina. Mild iridocyclitis developed in the other eye, and enucleation was performed two months after injury because sympathetic ophthalmia was feared.

Pathologic observations. There was a large hemorrhage in the posterior vitreous chamber, with organization over the disc involving the retina. The retina was partially detached and there was hemorrhage in the subretinal space. Hemor-

rhage in the anterior chamber and peripheral anterior synechiae were observed, but there was no evidence of sympathetic ophthalmia.

CASE 27. A.I.P. ACCESSION 136110

A bullet entered through the right zygomatic region and made its exit through the left. There was marked displacement of the left infraorbital plate, with downward displacement of the globe. The eye was enucleated ten weeks after injury.

Pathologic observations. The optic nerve was partially evulsed and the choroid had prolapsed into the arachnoid space. Organizing hemorrhage extended from the nerve head and adjacent choroid into the vitreous chamber.

INTERVAL OF THREE TO THIRTY MONTHS

In 20 eyes enucleated between three months and 2½ years following injury, the incidence of inflammation and secondary glaucoma was further increased, and there was one instance of equatorial staphyloma. Inflammatory pupillary and cyclitic membranes were seen and, for the first time in this series, calcium deposits in the lens and phthisis bulbi were observed.

CASE 28. A.I.P. ACCESSION 122877

The eye was hit by a fragment of exploding shell. Enucleation was performed three months after injury.

Pathologic observations. The remains of a hemorrhage were still present in the anterior chamber, and an organized hemorrhagic membrane covered the anterior surface of the iris. There were peripheral anterior synechiae. The ciliary processes were elongated and their epithelium proliferated. The retina was detached and had undergone gliosis.

CASE 29. A.I.P. ACCESSION 101964

The eye was struck by a stone. Cataract and secondary glaucoma resulted and enucleation was performed three months after injury.

Pathologic observations. There was chronic iridocyclitis with serous exudate in the anterior, posterior, and vitreous chambers. Iris bombé was present. The lens showed early degenerative changes. The lamina cribrosa was depressed from glaucoma.

CASE 30. A.I.P. ACCESSION 104773

After the eye was struck by a squash ball, repeated hemorrhages in the anterior chamber resulted in secondary glaucoma. Pain persisted despite repeated paracentesis. The eye was enucleated three months after injury.

Pathologic observations. The anterior chamber was almost completely obliterated by organizing hemorrhage which occluded the pupil. There were anterior and posterior synechiae and anterior displacement of the cataractous lens (fig. 7).

Fig. 7 (Rones and Wilder). Organizing hemorrhage in the anterior chamber occluding the pupil. Anterior displacement and degeneration of the lens. Hemorrhage in the vitreous chamber. $\times 12$. A.I.P. Negative No. 90125.

Hemorrhage in the vitreous chamber and in the subretinal space, chronic iridocyclitis, and secondary glaucoma were present.

CASE 31. A.I.P. ACCESSION 107046

A baseball had struck the eye causing

dislocation of the lens and secondary glaucoma. The eye was enucleated $3\frac{1}{2}$ months after injury.

Pathologic observations. There were chronic iridocyclitis and peripheral anterior synechiae. A small hemorrhage in

Fig. 8 (Rones and Wilder). Chronic glaucoma with equatorial staphyloma. $\times 2$. A.I.P. Negative No. 97213.

the vitreous was beginning to organize. An equatorial staphyloma was present with serous detachment and cystic degeneration of the retina at this point. Secondary glaucoma was evidenced by marked excavation of the optic disc (fig. 8).

CASE 32. A.I.P. ACCESSION 105295

A blow from a fist caused severe intra-ocular hemorrhage and secondary glaucoma. Tension was not lowered by posterior sclerotomy. The eye was enucleated four months after injury.

Pathologic observations. There were peripheral anterior synechiae, atrophy of the iris and ectropion uveae. The pigment epithelium was somewhat scattered and a few of its cells clung to the anterior surface of the iris. Anterior to the sclerotomy scar the ciliary body was atrophic, and posterior to it the retina was detached. The lamina cribrosa was depressed and there were atrophic changes in the

optic nerve. The lens was dislocated laterally.

CASE 33. A.I.P. ACCESSION 87772

After a blow from a fist severe intra-ocular hemorrhage occurred and endophthalmitis developed. The eye was enucleated $4\frac{1}{2}$ months after injury.

Pathologic observations. On one side, the iris was torn away from the ciliary body and almost completely replaced by scar tissue which extended across the anterior surface of the lens, incarcerated the iris pigment epithelium and sphincter muscle, and covered the anterior surface of the iris on the other side. The ciliary processes showed some hyalinization. Organizing hemorrhage extended across the anterior vitreous behind the lens, which was cataractous. There was microcystic degeneration of the retina, and the choroid was infiltrated by lymphocytes and plasma cells. The lamina cribrosa was somewhat depressed.

CASE 34. A.I.P. ACCESSION 88843

The blow of a fist caused hemorrhage in the eye. A traumatic cataract was removed two months after injury. Three months later phthisis bulbi had developed and the eye was enucleated.

Pathologic observations. The perforating, operative wound at the limbus had healed. The iris was absent and ciliary processes and scar tissue occluded the filtration angle. There was a large hemorrhage in the anterior chamber and there were serous and hemorrhagic exudates in the subretinal space and vitreous. The retina was detached and showed marked lymphocytic periphlebitis. Organizing hemorrhagic and inflammatory exudate was beginning to form a cyclitic membrane. The nerve head was pulled forward and the lamina cribrosa was not depressed.

CASE 35. A.I.P. ACCESSION 116864

Injury to the eye from an exploding land mine caused iridodialysis, vitreous hemorrhage, endophthalmitis, and secondary glaucoma. The eye was enucleated 5½ months after injury.

Pathologic observations. There were traumatic iridodialysis and vascularization of the anterior surface of the iris. The ciliary processes were adherent to the meshwork in the angle of the anterior chamber at the site of the iridodialysis. There was slight chronic iridocyclitis. Organizing hemorrhage was present in the vitreous. The optic nerve was atrophic and the lamina cribrosa depressed.

CASE 36. A.I.P. ACCESSION 87429

In an automobile accident the patient sustained a skull fracture and an arteriovenous aneurysm of the right internal carotid with resultant proptosis of the right eye. The eye was enucleated six months after injury.

Pathologic observations. A purulent corneal ulcer was secondary to paralysis of the trigeminal nerve and exposure. Serous exudate was present in the angle of the anterior chamber. The vascularity of the iris was greatly increased. Lymphocytes and plasma cells infiltrated the iris and the anterior ciliary body; the ciliary processes were edematous and their vessels engorged. On one side, there was peripheral detachment of the retina with subretinal serous exudate. Multiple hemorrhages had occurred in the nerve fiber and outer plexiform layers of the retina. The optic disc was cupped and filled with serous exudate, and the lamina cribrosa was depressed.

CASE 37. A.I.P. ACCESSION 115860

The eye was struck by a soccer ball, with resulting chronic iridocyclitis and phthisis bulbi. It was enucleated seven months after injury.

Pathologic observations. The iris had been ruptured, and its stroma replaced by organized hemorrhage which also filled the pupillary space. There was blood staining of the cornea. The lens was cataractous. Organizing hemorrhage filled the vitreous, and a plastic hemorrhagic and inflammatory cyclitic membrane had formed. Subretinal hemorrhage had caused retinal detachment. There were chronic endophthalmitis and beginning phthisis bulbi.

CASE 38. A.I.P. ACCESSION 105658

Injury to the eye by water under pressure caused repeated hemorrhages in the anterior chamber and secondary glaucoma. Paracentesis was performed, but endophthalmitis developed. The eye was enucleated nine months after injury.

Pathologic observations. An organized hemorrhage was present in the anterior chamber. The lens was cataractous. There was mild chronic iridocyclitis, with some disorganization of the iris pigment, and several posterior synechiae. The lamina cribrosa was depressed.

CASE 39. A.I.P. ACCESSION 113277

The patient was hit in the eye by a shoe and secondary glaucoma developed. A trephination and lens extraction were performed several months after the injury but the glaucoma persisted. The eye was enucleated 18 months after injury.

Pathologic observations. Fragments of proliferated lens capsule and cortex were incarcerated in the operative scar. There was mild chronic iridocyclitis with peripheral anterior synechiae. The pigment layer of the iris showed some destruction, with pigment-laden, wandering cells in the anterior and posterior chambers. The lamina cribrosa was depressed.

CASE 40. A.I.P. ACCESSION 113298

During training on an obstacle course,

the patient fell and struck his eye. Acute glaucoma necessitated iridectomy. The lens then became swollen and was removed 17 months after injury. Iridocyclitis developed. The eye was enucleated 20 months after injury.

Pathologic observations. The remaining iris tissue was adherent to the capsular and cortical fragments of the lens. Chronic iridocyclitis and a large intraocular hemorrhage were evident, and the lamina cribrosa was depressed.

CASE 41. A.I.P. ACCESSION 117649

The patient was struck in the eye while in commando training. The eye was enucleated two years after injury.

Pathologic observations. A traumatic, calcified cataract was present. There was chronic iridocyclitis, with wide anterior and posterior synechiae. The lens was displaced anteriorly and the anterior chamber was obliterated. There was an inflammatory cyclitic membrane and complete detachment of the retina, with massive subretinal serous exudate (fig. 9). Colloid excrescences were observed on Bruch's membrane.

CASE 42. A.I.P. ACCESSION 117900

The eye was struck by a baseball; cataract occurred, followed by recurrent inflammation and phthisis bulbi. The Kahn reaction was positive but became negative under treatment. The eye was enucleated two years after injury.

Pathologic observations. Anterior synechiae almost completely obliterated the anterior chamber. A dense mass of scar tissue occluded the pupil and formed an adhesion between the cornea, the anteriorly displaced lens, and the iris. There was an anterior capsular cataract, and the cortical lens fibers had degenerated. A granulomatous inflammatory process, in which foci of epithelioid cells with oc-

casional giant cells were sparsely surrounded by lymphocytes and plasma cells, involved the vascular layer of the ciliary body and the ciliary epithelium, forming adhesions to the lens. The retina was partially detached, was cystically degenerated, and contained serous exudates.

CASE 43. A.I.P. ACCESSION 110660

The blow of a fist caused cataract, chronic iridocyclitis, and phthisis bulbi.

Fig. 9 (Rones and Wilder). Inflammatory cyclitic membrane with detachment of the retina and subretinal serous exudate. $\times 2$. A.I.P. Negative No. 97212.

The eye was enucleated $2\frac{1}{2}$ years after injury.

Pathologic observations. A traumatic cataract contained calcium deposits. Chronic endophthalmitis had produced posterior synechiae and inflammatory pupillary and cyclitic membranes. The retina was detached and had undergone cystic degeneration; serous exudates were in and beneath it. Colloid excrescences were seen on Bruch's membrane. Phthisis bulbi had developed.

CASE 44. A.I.P. ACCESSION 122205

A baseball struck the eye, causing rupture of the iris, repeated intraocular hemorrhages, disorganization of the globe, and secondary glaucoma. The eye

was enucleated 5½ months after injury.

Pathologic observations. A coloboma of the iris was present, also anterior and posterior synechiae and a pupillary membrane. The ciliary body was atrophic and the lens cataractous. Secondary glaucoma was manifested by marked cupping of the optic disc.

CASE 45. A.I.P. ACCESSION 137517

A bomb explosion injured the right orbit, causing detachment of the retina and iridocyclitis. The eye was enucleated 3½ months after injury.

CASE 46. A.I.P. ACCESSION 130076

The eye was struck by an inner tube, with resulting iridocyclitis and traumatic cataract. It was enucleated nine months after injury.

Pathologic observations. A mass of scar tissue bound the atrophic iris to the cataractous lens, completely occluding the pupillary space. There was chronic iridocyclitis. The retina was edematous in the macular region.

CASE 47. A.I.P. ACCESSION 127493

The eye was struck by a slingshot.

Anterior				2
Lateral				1
Cystic Degeneration of Retina				2
Phthisis Bulbi				3

Pathologic observations. The iris was edematous, and there were wide posterior synechiae. The hemorrhage in the anterior vitreous had been partially phagocytosed. Chronic chorioretinitis and extensive cystic degeneration of the outer plexiform layer of the retina were present.

Cataract developed, followed by attacks of chronic iridocyclitis and then by secondary glaucoma. The tension was not relieved by an iris inclusion operation, and the eye was enucleated 18 months after injury.

Pathologic observations. The operative scar at the limbus was cystoid and there

was a traumatic cataract. Extensive serous detachment of the retina was associated with chronic iridocyclitis and secondary glaucoma, with marked excavation of the disc.

DISCUSSION

Table 1 is a recapitulation of the types of lesions resulting from recent nonperforating injuries to the eye. Intraocular hemorrhage is most frequent, and is variously situated depending upon the vessels damaged. Rupture of an iris vessel can cause a massive hemorrhage in the anterior chamber. In the posterior segment of the globe the site and extent of hemorrhage depend upon whether a ciliary, retinal, or choroidal vessel is ruptured.

Fig. 10 (Rones and Wilder). Traumatic iridodialysis, recent. $\times 10$. A.I.P. Negative No. 90131.

Concussion cataract was observed in 23 cases in this series, two of them in eyes enucleated the day they were injured. Such cataracts may be due to rupture of the lens capsule resulting from compression of the eye, which allows access of the aqueous to the lens fibers. Dislocations of the lens also occur, anteriorly, posteriorly, or laterally, depending upon the direction of the blow and the manner in which the suspensory ligaments are torn.

A blow upon the anterior surface of the globe pushes the aqueous backward and to the side. Since the aqueous cannot be compressed, the force is reflected backward against the iris and the lens, causing them to recede or tear where they are

weakest; namely, at the iris root and through the zonular ligaments (figs. 10, 11, 12). Such an iridodialysis commonly involves only a portion of the circumfer-

Fig. 11 (Rones and Wilder). Traumatic iridodialysis, recent, with hemorrhage into the anterior and posterior chambers. $\times 35$. A.I.P. Negative No. 90154.

ence of the iris root, although the circumferential tear may be complete.

The force of a blow from a blunt instrument on the anterior segment of the globe may also be dispersed so as to cause rupture of the pupillary margin of the iris, including the sphincter, or rupture of the filtration angle. The force of such a blow may be reflected posteriorly to produce detachments of the retina, the choroid, and the ciliary body. In addition,

Fig. 12 (Rones and Wilder). Traumatic iridodialysis with beginning closure of the coloboma by organizing hemorrhage. $\times 30$. A.I.P. Negative No. 90127.

evulsion of the optic nerve has been encountered in three cases of this series.

Secondary glaucoma was a frequent sequel to contusion injuries, and resulted from massive hemorrhage, dislocation of the lens, or synechiae following recurrent nonpurulent endophthalmitis. The optic nerve may early show the effects of this increased pressure; in one case the lamina cribrosa was depressed six weeks after

was precipitated by recurrent iridocyclitis or hemorrhages. These eyes were blind in all cases, and prolonged and recurrent pain was the reason for their enucleation. As is to be expected, many of these eyes have the scars of operations, which had been performed to lower intraocular pressure, to remove cataracts or dislocated

injury. Advanced glaucomatous excavation and atrophy may develop within a few additional weeks if the intraocular pressure is considerably elevated.

The 57 eyes of this series with non-perforating injuries incurred before induction into the Army are analyzed as a group. The time interval between injury and enucleation varied considerably: the shortest was four years, the longest, 28 years. The most frequent cause of enucleation was the development of secondary glaucoma, although in many cases it

lenses, or to repair detached retinas. Thus in these eyes the effect of surgery was superimposed upon the original trauma.

Table 3 shows the most common pathologic findings in these eyes. Chronic endophthalmitis was the most frequent, with cataract, detachment of the retina and choroid, and secondary glaucoma following in that order. A great variety of degenerative and late inflammatory changes were recorded, including pig-

epithelium (fig. 16), atrophy of the ciliary body (fig. 17), colloid excrescences on Bruch's membrane (fig. 18), ossification of the choroid (fig. 19), hemorrhages and obliterative vascular changes in the retina, and retinal gliosis (fig. 20), and cystic degeneration (fig. 21).

The cases in this series that held the greatest interest for us were 20 in which inflammatory reactions followed contusion injuries not complicated by operative

Fig. 22 (Rones and Wilder). Granulomatous cyclitis. Nodular aggregations of epithelioid cells in the vascular layer and epithelium. $\times 95$. A.I.P. Negative No. 90148.

procedures. Purulent endophthalmitis was encountered twice, both times in eyes with traumatic laceration of the optic nerve. Within a period of two weeks, purulent keratitis had developed, as a result of exposure or of neurotrophic disturbance. In the first case the purulent reaction extended into the anterior chamber and involved the iris. Here the inflammation was chiefly confined to the anterior segment, although there were some leukocytes in the vitreous hemorrhage and around the vessels in the orbital tissue. The second case exhibited a ring abscess of the cornea, with purulent exudate in the anterior chamber extending into the anterior vitreous and back along the retina. The purulent reaction involved the optic nerve and its sheaths. The mechanism which produced the purulent endophthalmitis is easily comprehended; it undoubtedly proceeded by direct extension from the purulent corneal inflammation and was in no sense a blood-borne infection.

A granulomatous inflammatory reaction was seen only once, and then in the case of a soldier with a positive Kahn reaction. The history was that following contusion of the eye, recurrent inflamma-

tion set in and a complicated cataract developed, passing over into phthisis bulbi. Pathologic examination showed dense scar tissue occluding the pupil and forming an adhesion between the cornea, the iris, and the cataractous lens. The ciliary body and its processes were the sites of a granulomatous inflammatory reaction, in which foci of epithelioid cells with occasional giant cells were rather sparsely surrounded by lymphocytes and plasma cells (fig. 22). The interpretation of this lesion raised certain questions. Was there a quiescent focus in the ciliary body which was stirred into activity by the trauma? Did trauma provoke the granulomatous lesion in an individual with systemic syphilitic disease? It is impossible to answer positively, for the problem is still in dispute in medicolegal spheres.

Active endophthalmitis was manifested in an eye enucleated seven weeks after a gun-powder explosion. There was dense lymphocytic infiltration around Schlemm's canal, with lymphocytes and plasma cells around the vessels of the intrascleral plexus and in the spaces of Fontana (fig. 23). Chronic inflammatory

Fig. 23 (Rones and Wilder). Active endophthalmitis with lymphocytes and plasma cells in the iris, filtration angle, and spaces of Fontana. Aggregation of lymphocytes around the canal of Schlemm. $\times 160$. A.I.P. Negative No. 90141.

cells and polymorphonuclear leukocytes clung to the posterior surface of the cornea and to the anterior surface of the iris. Chronic inflammatory cells infiltrated the iris, the ciliary body, the inner layers of the retina, and the nerve head. There was perivascular lymphocytic infiltration in the retina (fig. 24) and nerve head (fig. 25), with a few polymorphonuclear leukocytes in the inner layers of the retina. The intensely cellular nature of the inflammatory response is in marked contrast to that seen in a number of other cases, and led us to regard the condition in this case as a response to infection.

In 16 cases in this series the inflammatory response was definitely a reaction to the tissue trauma and subsequent hemorrhage. These cases of traumatic uveitis appear to be more severe than the inflammations resulting from infections and more frequently lead to enucleation, either because severe inflammation recurs or secondary glaucoma ensues. In this series six eyes were enucleated because of glaucoma, while ten were removed for recurrent iridocyclitis. The mechanism of production of the inflammatory lesions is not simple. Unquestionably the injury and destruction of tissues can liberate toxic substances which induce an inflammatory response. In the same way, intraocular hemorrhage can act as an exciting agent. There are two less likely factors which nevertheless have

Fig. 24 (Rones and Wilder). Lymphocytic periphlebitis in the retina. $\times 130$. A.I.P. Negative No. 94128.

Fig. 25 (Rones and Wilder). Lymphocytic perivasculitis in the optic-nerve head. $\times 60$. A.I.P. Negative No. 90142.

their proponents; namely, reflex nerve irritation and allergic sensitivity to dispersed uveal pigment or lens proteins. In two of these cases there were enough infiltrating eosinophils to suggest an allergic factor. In the remaining cases the inflammation was predominantly in the anterior segment in 12; in the posterior segment in two. The paucity of cellular response in such traumatic uveitis without penetrating wounds was in contrast to the cellularity of infectious uveitis. Lymphocytes and plasma cells were the dominant cell types, and they were scantily infiltrated through the iris, ciliary body, or choroid. These cells were also noted in the anterior chamber, on the posterior corneal surface, and in the vitreous, particularly around the ciliary processes. The exudative response to inflammation in these cases was more marked than the cellular, and was manifested by the formation of anterior and posterior synechiae, together with pupillary and cyclitic membranes. The pigment layers of the iris, ciliary body, and retina simultaneously exhibited areas of degeneration, with scattering and phagocytosis of pigment adjacent to areas of extensive proliferation of the fixed chromatophores.

SUMMARY

This report has dealt with 104 cases of nonperforating ocular injuries in sol-

diers. Forty-seven eyes were injured during combat or training. The interval between injury and enucleation varied from less than one day to $2\frac{1}{2}$ years. In these eyes, hemorrhage was the most frequent finding, although nonpurulent endophthalmitis, detachment of the retina, and secondary glaucoma also were often noted. Injury to eyes of 57 soldiers had preceded induction into the Army. The shortest interval between injury and enucleation in this group was four years and the longest 28 years. Chronic endophthalmitis was the most frequent finding, with cataract, detachment of the retina and choroid, and secondary glaucoma following in that order. A great variety of degenerative and late inflammatory changes were recorded.

An inflammatory reaction was present in 20 cases in which no operation had been performed. Purulent endophthalmitis in two of these had resulted from intraocular extension of purulent keratitis. A granulomatous inflammatory reaction was observed in the ciliary body and

processes of a third. The most striking cellular response was observed in a fourth case, in which there was active endophthalmitis, with dense lymphocytic infiltration around Schlemm's canal and chronic inflammatory cell infiltration in the iris, ciliary body, retina, and nerve head. This reaction was regarded as a response to infection. In the remaining 16 cases the inflammation was clearly a response to tissue trauma and subsequent hemorrhage, although in two the number of eosinophils in the infiltrate suggested an allergic factor. The inflammatory process was chiefly in the anterior segment in 12 cases, and in the posterior segment in two. The paucity of the cellular response was noteworthy; lymphocytes and plasma cells were the dominant cell types. On the other hand, the exudative response was marked and resulted in the formation of anterior and posterior synechiae together with pupillary and cyclitic membranes.

SOME OBSERVATIONS ON THE SURGICAL TREATMENT OF THE EXTRAOCULAR MUSCLES*

AVERY DEH. PRANGEN, M.D.

Rochester, Minnesota

It is interesting and useful to look back over one's experiences and efforts in any field of endeavor, and try to analyze and evaluate them. In doing surgery on the muscles of the eyes, we all have our successes and also failures. Our successes are a most gratifying reward, while our failures are a disappointing stimulus encouraging us to eliminate our imperfections. I have the feeling that it is often from our unsuccessful cases that we learn the most. The constant search for the causes of failures goads us on to improvement. In this paper I am making no report of percentages of successes and failures. Many careful and excellent analyses of results already have been made, and I would anticipate that our figures would closely parallel those of previous studies. I would rather discuss factors and themes concerning surgery of the muscles of the eyes and the possible relationship of such factors and themes to success or failure.

UNDUE CONSERVATISM A HANDICAP

As number one in my own causes of failure I would list undue conservatism. By this I mean hesitation to operate when surgery is indicated and, more important, *not being radical enough* in my procedures while operating. Although this may well be a personal fault, I have observed it to be a frequent one among other surgeons operating on muscles of the eyes. My generation of ocular surgeons was brought up that way. It was the natural result of coming into ophthalmic surgery after the period of disastrous "free"

tenotomies of the ocular muscles. The operation of recession and the various forms of satisfactory shortening operations had not been perfected, and we were greatly handicapped by inability to operate on the eye muscles safely, accurately, and yet adequately. The situation made us too conservative in our surgical approach, and I for one have had great difficulty in overcoming it.

At the present time there is no need for this excessive conservatism in respect to when to operate and how to operate. The operation of recession has become thoroughly proved and established. It is a simple and safe operation, capable of control by measurement, and can be performed on the eyes of young children and also adults. Likewise, various simple, safe, and accurate resection operations are in use for eyes of persons of any age. The use of absorbable gut sutures has further simplified operation and post-operative care. Also, general anesthesia for young children and adults has progressed to a point of minimal danger and minimal operative annoyance. Therefore, we need not be inhibited as to when to operate or how to operate because of doubts as to safety and accuracy.

To me, this has been the outstanding achievement of this generation in surgery of the muscles of the eyes. The lack of this assurance was the outstanding handicap of my earlier career in this type of surgery. I am most thankful that the younger men of today and tomorrow need not be so troubled.

BE RADICAL ENOUGH TO ATTAIN OBJECTIVES

In operating, we must always have due regard for minimal trauma to tissue and

* From the Section on Ophthalmology, Mayo Clinic. Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

yet we must be radical enough in our efforts to attain our objectives. Often the most radical surgery is the best and least traumatizing. In my earlier years, trying to assure minimal damage, I handicapped my efforts by small, "stingy" incisions and inadequate dissection or exposure of essential structures in the field of operation. This fault I have observed often in others.

Before reconstruction and alteration of tendons and muscles can be properly carried out, it is necessary to visualize freely and to study the tissues to be altered. Incisions heal crosswise and not lengthwise. Therefore, a long incision permitting wide exposure and free visualization is best. As pointed out by Jameson,¹ Kirby,² and others, the condition of tissues as found at operation often determines or alters the type or extent of the surgery to be performed. If we do not "open up" wide enough, we cannot see these tissues.

Again I repeat, in reconstructing tendons and muscles we must be radical enough to attain our objectives. I have failed too many times through timid or halfway measures. The early teachings of my generation to be "careful" and not to do too much caused me, at least, too many failures or partial successes. It has been my experience that overcorrections of muscular defects have been very few indeed; whereas, undercorrections or partial successes have been far too common. Personally, I should much prefer an occasional overcorrection and to reoperate for it than to wonder what to do next for frequent halfway or partial results. In truth, many postoperative conditions which are somewhat overcorrected, in our opinion as ophthalmic surgeons, are in fact most acceptable to the patient and family; whereas, many conditions which to us are somewhat undercorrected are certainly unsatisfactory to the patient, the family, and ourselves.

RECOGNIZE TYPE AND DEVELOPMENT OF TISSUES

The importance and characteristics of the various tissues encountered during an operation should be considered. The conjunctiva, or protective coat of the globe, is the point of entrance and the means of closing the surgical wound. It should be incised cleanly and widely, and at the proper points, so that it can be smoothly replaced and evenly closed with adequate sutures. Failure to do these things invites sloughing wounds, with excess granulation and poor healing. Improper conjunctival cicatrization may adversely affect the result of an operation on ocular muscles and vice versa.

Tenon's capsule is a key structure in operation on muscles of the eyes. This fact has been called to our attention by Jameson¹ and by Berens and Romaine.³ Jameson stated that Tenon's capsule could be utilized to reinforce poorly developed muscles or that it could be altered so as to lessen the action of hypertonic muscles. Berens and Romaine called attention to the necessity for preservation and conservation of Tenon's capsule; they said that, when operation is performed, Tenon's capsule over the muscles should be preserved so as to minimize postoperative adhesions of tendon and muscle to the sclera. Such adhesions, when excessive, tend to defeat our operative efforts. With the observations of these authors I am in thorough accord.

It goes without saying that the type and development of tendon and muscle encountered materially affect our decision as to what and how much to do surgically to the tendon and muscle. Preoperative ideas concerning the nature of these structures may have to be changed at the time of surgical exposure. The exact power or tension of muscles can be determined only at operation. Occasionally, anomalous insertions and attachments of

tendons and muscles to the sclera are encountered and have to be corrected. I have encountered insertions at abnormal distances and abnormal angles from the corneal limbus, accessory or double-headed tendons, abnormal formations in Tenon's capsule, and bands of tissue connecting the belly of the muscle with the sclera. All of these can be found only by wide exposure and free visualization. Some of these structures, I believe, are phylogenetic. Unless due recognition is given to these anomalous conditions and proper disposal of them is made, results will not be good.

PROPER DIAGNOSIS A PRELUDE TO SURGERY

Proper diagnosis is a necessary prelude to performance of any type of surgery. To operate without knowing what is wrong is, of course, absurd. Many times, however, in complicated cases of imbalance it seems impossible to make an exact diagnosis and we are forced to operate with an incomplete diagnosis. We should strive, however, to come to as nearly exact a diagnosis as possible before operating. As a rule, the need for operation is not urgent. When the condition is doubtful and observations are mixed, repeated observations can be made over a period sufficient, as a rule, to give us a fairly accurate idea of what is wrong before we operate. When the diagnostic picture is not clear, I prefer to delay surgery. Delay and repeated observations often clear up the diagnosis and also often change the original diagnosis for a better one.

The general theme of diagnosis of muscular anomalies has been universally established by many writers, such as Howe, Duane, Jackson, Verhoeff, Lancaster, White, and others. No one method of diagnosis is infallible. We all have our own diagnostic tricks,

In general, I believe there is no substitute for watching "eyes move" in making a diagnosis. Movement of the eyes binocularly and monocularly, and notation of their behavior with the cover test, have been my most useful procedures.

Diagnosis by means of prism measurements and cover test has not been too useful to me. Probably I have not become proficient enough in this method. However, as I have done it and watched it done by others, I have been skeptical of the findings and of the diagnosis of vertical anomalies in the oblique fields as found by this method of diagnosis alone. To my mind, the oblique fields of movement of the eyes are unstable and too many bizarre findings and diagnoses were made in the oblique fields by this method of diagnosis which I could not substantiate by observing the eyes move in these fields. At least, I have been unable to consider it safe to proceed to operate on the vertical muscles as diagnosed by screening and prism measurements alone. Undoubtedly, prism measurement and screening are useful adjuncts to our diagnostic procedures but, as Lancaster⁴ stated, "much time is expended on irrelevant, unnecessary, although not uninteresting measurements."

In a previous paper,⁵ I summarized what I thought to be the essential data in trying to make a diagnosis in muscle anomalies. These are: (1) The visual powers for distance and near vision are essential. (2) The refractive error and accommodative needs are studied. (3) The movements of the eyes in the various fields of fixation, with and without the cover test, are observed. (4) The convergent near point is taken. (5) Fusion is investigated. (6) Rest positions or phorias for distant and near vision are noted and compared. (7) Vergence powers are determined. (8) The character of any existing diplopia is studied. (9)

Symptoms are evaluated and the individual is classified medically, neurologically, and sociologically. (10) Repeated observations are made.

By a thoughtful assembling of these facts it should be possible to arrive at a definite diagnosis. Improvement in diagnostic methods based on a better understanding of the physiology of ocular motility has been of tremendous help in improving our surgical results. It is much easier to select the proper operative procedures in a given case after a refined differential diagnosis has been made.

The goal of operative treatment is to restore function, not merely to straighten eyes. When eyes are made to function properly, they will be straight. Often there are several types of surgical procedure which will straighten a pair of eyes. The best type should be the one which works toward assisting in restoration of function. Careful study of the existing state of function of the muscles of the eyes is a great aid in selection of the type of operation to be performed. I discussed this more fully in a previous paper.⁶ It is probably by a combination of all methods of diagnostic procedure that we obtain our best results. When all our data are thoughtfully and carefully assembled, the diagnostic picture will take form. I often liken the procedure to the working out of a crossword puzzle. The answer, after much doubt, suddenly becomes clear.

INDICATIONS FOR OPERATION

When imbalance is variable, particularly if it is improving, operation should be deferred. On the other hand, when imbalance is becoming worse, operation is indicated sooner. In children, particularly, and in adults, when the diagnosis is obvious and there is no favorable response to nonoperative treatment, there is no ex-

cuse for delaying operation. To delay is only to make matters worse. We have the means at hand to operate safely and accurately, regardless of age. The establishment of the recession operation, simple resections, the use of gut sutures and modern anesthesia have made such safety possible.

When strabismus is severe, particularly in children, and prolonged nonoperative measures cannot be carried out, it is often advisable to operate and put the eyes into position in which they can help themselves to straighten, rather than to allow them to be neglected.

In dealing with children it is well to remember, however, that the young, growing mechanism has an inherent tendency to correct itself with a minimum of surgical help. How many times has one seen unilateral recession of a rectus medialis muscle correct convergent strabismus in a child when one felt positive that both of these muscles would have to be recessed!

On the other hand, if the patient is an adult, minimal surgical assistance rarely is enough. Among adults one is dealing with a deformity which has become firmly fixed. It seems to me that in operating on the extraocular muscles one must be "radical and yet accurate," and must try to visualize the underlying physiologic condition and its pathologic changes.

When an eye has been operated on by a colleague for imbalance, *apparently* without success, let us not be too quick to judge his work a failure. Even if the eyes still deviate, his work may have been well done. Perhaps the degree of strabismus was too great to be corrected by operation on one eye. The other eye may have needed operation, and the surgeon may have planned his procedure that way, to complete the result. Before advising reoperation on the same eye, one should inspect its motility and scars, considering

the possibility that it has been properly operated on and all has been gained that it was possible to gain in one eye. Operation on the other eye probably will complete the correction and, if this is successful, one should insist that the patient give credit to both surgeons. I have had a number of such cases.

When muscular imbalance is complicated, as in combined lateral and vertical defects or a mixed bilateral involvement, I believe that operation for the the obvious or outstanding defect should be performed first, and that the other doubtful muscle or muscles, or the other eye, should be left for subsequent observation and possible operation later.

Often, when the worst offending muscle, muscles, or eye is operated on, the lesser offender, or the other eye, will adjust itself and further operation will not be needed or may be much less extensive than originally anticipated. It is the old principle of attention to first things first. In other words, imbalance of a vertical muscle may disappear after a pronounced defect of a lateral muscle has been corrected. Or the circumstances may be the other way around, imbalance of a lateral muscle vanishing with correction of a defect of a vertical muscle. Also, the fellow eye may straighten after the worse eye has been corrected.

Much has been said in the literature concerning inability to straighten and hold straight, by surgery, eyes with anomalous retinal correspondence. I have found this to be true only of eyes which have extreme amblyopia and marked eccentric fixation. When deviating eyes are able to fixate properly, I have found that they respond satisfactorily to cosmetic surgery, regardless of anomalous retinal correspondence. However, when deviating eyes fixate eccentrically, I have found that they do not remain straight after cosmetic surgery and that they have a marked

tendency to return toward their previous position of deviation.

TYPES OF OPERATIONS PERFORMED

I prefer that the patient be under the influence of general anesthesia for practically all my operations on muscles of the eyes. When this type of anesthesia is employed, the patient is at ease and so am I. I have found local anesthesia to be unreliable, unpredictable, and unsatisfactory. I cannot do my best work when the patient is conscious of pain. Extensive local injections disturb the field and interfere with the delicate and extensive dissections which I feel are necessary to obtain good results. The intratracheal type of anesthesia has proved highly satisfactory in my experience. If the patient is a very small child, the tube is hung in the angle of the mouth instead of being passed into the trachea.

As to the types of operation performed on the various muscles, I have finally adopted a simple form of resection or recession procedure on the rectus muscles, except in the case of the lateral rectus muscle which I still tenotomize in most instances. In tenotomizing the lateral rectus muscle, I cut only its primary insertion from the sclera, and I carefully avoid disturbing its other attachments to the sclera and capsule.

For more than 10 years I have used only plain gut sutures in all operations on muscles of the eyes. The "plain" catgut 3-0 or 4-0 has been found to be satisfactory. These sutures, in my experience, have caused the least reaction, hold sufficiently long, and do not have to be removed. All knots are tied outside the conjunctiva, so that a minimal amount of suture material is left buried. Enough extra sutures of the same material are used to close completely the conjunctival wound. This minimizes granulation.

In suturing the rectus muscles to the

sclera I use two sutures, the Worth type in resection and the Jameson ligating type in recession. Each suture includes half of the tendon. The inferior oblique muscle I tenotomize or recess at its insertion on the globe. The superior oblique muscle I have not operated on, but I am very much interested in the paper on this subject delivered by Dr. Berke⁷ at this meeting. I have found transplantation of part of the adjacent rectus muscles to the stump of a resected paralyzed fellow rectus muscle to be successful in about 50 percent of cases in which the procedure has been tried. I regard the operation as well worth while. The O'Connor cinch operation produces satisfactory results in competent hands. So far, I have not been converted to its use because the operation, as usually performed, disturbs and discards Tenon's capsule. As stated earlier, I prefer to preserve and utilize Tenon's capsule when operating on muscles of the eyes.

A mistake which I and others make occasionally while operating on muscles of the eyes is failure to isolate *all* of a tendon and muscle. Probably because of inadequate exposure, the tendon is split and only a portion of it is picked up and isolated for reconstruction. One remarks that the tendon and muscle are small and poorly developed. Of course, if only a portion of the tendon and muscle is altered, the operation will be a failure. To avoid this error, if one opens up the field of operation widely and continues dissection until there is no doubt as to the inclusion of the whole tendon and muscle, this mistake will be avoided. I mention this because I have seen it happen to me, to my assistants, and to other surgeons.

In resection of the rectus muscles, how much shall we resect? I have cause to feel that we should resect enough to take up the "slack" or "give" in the muscle. With the muscle completely freed from all

global and conjunctival attachments and held forward on the muscle hook, the Prince forceps is shoved backward until the muscle in the forceps is under distinct tension. Measurement from the hook to the back of the forceps, where the sutures go, usually shows, in the case of the lateral rectus muscle, from 10 to 11 mm. of tendon have been resected by this method. In the case of the rectus medialis muscle this measurement is from 8 to 10 mm.; in the case of the inferior rectus muscle, from 5 to 6 mm.; in the case of the superior rectus muscle, from 5 to 6 mm. If the muscle is paralyzed and flabby, these measurements will be several millimeters higher. Such radical resections really get results. I have the feeling that small resections usually are failures. Rarely in my experience has even slight strabismus been corrected by a single resection or recession operation in adults. It is usually necessary to operate on more than one muscle of the same eye or on the fellow eye in adults.

In recessing rectus tendons, I have found small recessions to result in failure. The medial rectus muscle I recess 5 mm., no more and no less. The external rectus muscle, due to its long arc of contact with the globe, is difficult to weaken. I recess 7 to 8 mm. when I perform the recession operation on the muscle. The inferior rectus and the superior rectus muscles I recess from 4 to 5 mm.

Operations on the oblique muscles have been described by Wheeler,⁸ Berens and Loutfallah,⁹ Dunnington,¹⁰ White,¹¹ Guibor,¹² Hughes,¹³ Wagman,¹⁴ and Berke.⁷ There is an increasing, and I think correct, tendency to perform radical reconstruction of these muscles so difficult to operate on. The oblique muscles are difficult to treat surgically because of their obscure and peculiar anatomic relationships. In operating on them one must be persistent in dissection and carry

it on to the point at which these muscles are as completely freed and visible as the rectus muscles are when they are operated on. When this is done, the oblique muscles can be easily altered at will. At least, I know this to be true of the inferior oblique muscle, and Dr. Berke's paper shows that it is likewise true of the superior oblique muscle. In surgical treatment of the inferior oblique muscle, I have found it best to operate on it posteriorly, at its insertion on the globe.

Results achieved by the anterior approach, through the lower lid, have been very disappointing. Results obtained from the posterior or global approach have been much better, especially since I have been recessing the tendon. Recently, I have been setting the "completely" freed tendon of the inferior oblique muscle forward on the horizontal meridian of the globe to a point 6 to 7 mm. posterior to the middle of the point of attachment of the rectus lateralis muscle. This places the attachment of the inferior oblique tendon close, or slightly posterior, to the end of the theoretic horizontal axis of elevation and depression of the globe. With the inferior oblique tendon anchored to the globe at this point, the muscle should have very little power to elevate the eye when the eye is adducted. I have found, in the few cases in which I have carried out the procedure, that this method of reducing the action of the inferior oblique muscle is very successful. I recommend that it be given a trial. To allow the inferior oblique muscle to become attached anywhere on the posterior inferior quadrant of the globe, as it will become attached after tenotomy or tenectomy, seems to me to invite failure. In anchoring the inferior oblique tendon to the sclera, I use one suture of plain catgut (4-0) tied completely around the tendon and then woven through it and left buried.

As already stated, I regard tendon transplantation to be well worth trying in the treatment of paralysis of the rectus muscles, particularly in the case of the lateral rectus muscle. In my experience, excellent motion is obtained in the paralyzed field in about 50 percent of cases in which the aforementioned procedure is performed. When the transplants fail to act, the eye will be cosmetically straight because of the "extensive" resection performed on the paralyzed muscle and the partially crippling recession performed on the opposing muscle. In the case of a paralyzed rectus lateralis muscle, I resect the paralyzed muscle a maximal amount—13 to 15 mm.—and recess the opposing rectus medialis muscle 6 mm. The technique of the operation has been described in several excellent articles by various authors such as O'Connor¹⁵ and Lutman.¹⁶

POSTOPERATIVE MANAGEMENT OF PATIENTS

The immediate postoperative management of patients who have undergone operations on muscles of the eyes seems to be an individual problem. Each surgeon has his own ideas and routine, which he feels return to good condition the eyes which have been subjected to operation. It seems to me that eyes which have been operated on recover very satisfactorily regardless of which postoperative regimen is followed.

If an eye on which an operation has been performed is kept clean "outside" and reasonably quiet for a few days, it will progress satisfactorily. Dr. Edward Jackson once told me that if the eyelids and eyelashes were kept clean, adequate drainage would be established naturally. In other words, irrigation of the eyes is unnecessary. In recent years I have followed this advice. At the Mayo Clinic our postoperative care is simple, based on

minimal disturbance of a part recently operated on. The eyelids and eyelashes are cleansed, some form of ocular antiseptic agent is instilled and pads are applied. The eyes are not irrigated. I believe that it is better not to interfere with the chemical content of the conjunctival cul-de-sac. Our postoperative reactions have been definitely less since we ceased to use postoperative irrigation of the conjunctival cul-de-sac. When marked reactions are encountered, I have found that the intramuscular injection of boiled whole milk is effective in shortening the duration of the reaction. Usually, only one injection of milk is given.

The long-range postoperative management of patients who have undergone operations on muscles of the eyes is of more interest. There is no doubt in my mind that intelligently directed orthoptic treatment must be of definite value in the postoperative care of such patients. My use of such treatment has been limited, but enough to convince me of its value. Orthoptic treatment to cure some muscular defects may make operation unnecessary and its use to assist in refining the diagnosis in all cases of muscular defects is of unquestioned value. Postoperative orthoptic treatment should be ideal to

complete a cure in selected cases, but not in all. In adults, particularly, and also in children, in the presence of postoperative diplopia and persistent fusion "inability," I think orthoptic treatment should be studiously avoided. Orthoptic treatment in such cases is not only futile, in my observation, but may also tend to fix the diplopia and to keep the patient confused and unhappy. Postoperative diplopia and fusion inability, I believe, are managed best by the absence of orthoptic treatment. It is sometimes best to let sleeping dogs lie. I have seen a considerable number of patients who had so-called horror of fusion, with eyes that had been intensively trained orthoptically after surgical treatment of muscles of the eyes. These patients have been very unhappy people. I think the best treatment for postoperative diplopia among patients who have undergone operations on the ocular muscles is to ignore it, unless the diplopia responds immediately to orthoptic treatment.

I have tried to draw, from my own experience in operating on the muscles of the eyes, some conclusion which might be useful, especially to the younger ophthalmologists interested in surgery of these particular muscles.

102-110 Second Avenue, S.W.

NOTES, CASES, INSTRUMENTS

CLINIC FOR BINOCULAR PROBLEMS*

OBLIQUE ANISEIKONIA WITH LEFT HYPERPHORIA AND CYCLOPHORIA

PAUL W. MILES, M.D.
Hanover, New Hampshire

Mr. R. A. B., Case 13579, a bank clerk, aged 24 years, was first seen at the Dartmouth Eye Institute in September, 1941, and his case has been followed for five years.

His chief complaints were eyeache and

Examination. The patient habitually tilted his head toward the right shoulder. Pupils were normal. Tension was normal to palpation. Ophthalmoscopy showed myopic conus present. Visual acuity was 20/200 in either eye, without correction.

Prescription. Previous correction had been: R.E., with a $-1.50D.$ sph. \ominus $-2.50D.$ cyl. ax. 168° , 20/50; L.E., with a $-1.00D.$ sph. \ominus $-3.50D.$ cyl. ax. 30° , 20/50. The new noncycloplegic refraction was: R.E., with a $-1.00D.$ sph. \ominus $-3.50D.$ cyl. ax. 170° , 20/30; L.E., with a $-1.00D.$ sph. \ominus $-4.00D.$ cyl. ax. 17° ,

Eso. 3, L.H. 2 p.d.	Eso. 2, L.H. 1 p.d.	Eso. 2, R.H. 1 p.d.

* Prism diopters.

fatigue, frontal and temporal headache almost daily, burning and watering of the eyes, inability to see in bright light, occasional double vision (especially at night), inability to read more than one-half hour without eyestrain, fatigue and headache at the movies, inability to judge distances, floating black specks after use of the eyes.

History. He stated that he had had poor vision since childhood, but the aching and other complaints had become progressively worse the previous two years, until he was forced to change his occupation. He stated that he was never able to drive a car with confidence, driving "on nerve." He would have gone to college if it had not been for his weak eyes. The family history and past medical history were noncontributory.

20/30. Motility with the correction was: Distance: Eso. 1, L.H. 1 (prism diopter); Near: Eso. 4, L.H. 3 to 4. Amplitudes of fusion were: Distance: Convergence, 14/8 (break and recover); divergence, 7/5; vertical, $+1/0$ (base down right); divergence, $-4/3$ (base up right). Near: Convergence, 12/10; divergence, 16/12. Stereopsis was 90 percent on the Keystone DB6 card. He was given the above refractive prescription.

On February 12, 1943, the patient returned with the same complaints as before, reporting very little comfort. The refractive error, hyperphoria, and acuity were unchanged.

The diplopia fields with red glass over the right eye, as shown in Table 1, would indicate excyclophoria.

On the Bielschowsky cyclophoria device there was found right conclination of 1.6 degrees, and left disclination of 5.5 de-

* From the Dartmouth Eye Institute.

grees (axis top inclining laterally).^{*} The new refractive correction was: R.E., with a $-1.25\text{D. sph. } \ominus -3.50\text{D. cyl. ax. } 170^\circ$, 1^{Δ} diopter (base up); L.E., with a $-1.00\text{D. sph. } \ominus -4.00\text{D. cyl. ax. } 17^\circ$, 1^{Δ} diopter (base down). Space eikonometer findings with this prescription were: $\times 90$: L 0.8 percent ± 0.5 degrees; $\times 180$: L 0.8 percent ± 0.5 degrees; δ : -1.0 ± 0.5 degrees. Slight overall magnification was required for the left eye and there was considerable oblique aniseikonia due to the oblique astigmatism present.

Amplitude of fusion with this correction was: Distance: Divergence, $8/6$; Convergence, $16/10$; vertical divergence, $3/2$. Near: Convergence, $16/11$; divergence, $16/12$. Stereopsis was 90 percent on the Keystone DB6 card (with difficulty).

Results. On March 28, 1943, the patient reported by letter, after wearing prisms but no aniseikonic correction for seven weeks: "The effects of the new lenses have been varied. I could not wear them steadily for two weeks, during which time I kept going back to the others when pain or tiredness occurred. At the end of two weeks I could wear them all of the time. To see anything I have to stare and adjust myself to it; however, I see more of it than ever, very clearly and very sharp. Through the outside edges I see double, the result being I must look through the center all of the time. Tiredness and discomfort come up as before, but is possibly delayed a bit. Also when tired my eyes water. This is really a new experience.

^{*} Note that an emmetropic, noncyclophoric pair of eyes would have cyclophoria for horizontal-line objects if such refractive oblique cylinders as this are worn, and that the nearer the horizontal the cylinder axes become, the less would be the cyclophoria measured. Try this with a Maddox rod before each eye and a prism base down before one eye to make two horizontal lines. The lines will be made parallel (and thus suitable for fusion) by exocycloverision.

"Changing my focus takes more time than I have experienced, especially going from a broad field to a detailed surface. That is, looking relaxed about the room then returning to a typed letter before me; it appears a jumble and I have to stare at some part of it to locate my focus. In writing now, as has been the case if I center the focus in the paper, the upper left hand corner will tend to rise. Also when looking fixedly at a distant object everything about seems out of focus, which requires additional effort to bring it into clear view.

"Moving pictures are very tiring, and have brought on headache unless I was seated in the center. Slight nausea has occurred also. This occurs also when tiredness comes about. Light effects me as it always has. In the rear of a high ceilinged, brightly lighted hall, my vision to the other end is greatly cut off and the reflection of all the lights is carried on the glasses."

On April 13, 1943, he was tested on the ophtho-eikonometer and again on the space eikonometer. Meridional or overall aniseikonia was not found on the ophtho-eikonometer, but the space eikonometer detected oblique aniseikonia.

He was given 2-percent meridional aniseikonic fitovers converging out (that is, R.E., $\times 135$; L.E., $\times 45$). He reported the next day that the floors looked level, but a back wall or movie screen tipped toward him (overcorrection). There was less "confusion" on looking from one object to another than without the aniseikonic fitovers. He was, therefore, given the following aniseikonic fitovers: R.E., 1.5 percent $\times 135$; L.E., 1.5 percent $\times 45$.

On April 22, 1943, he reported by letter: "This prescription is the best I have yet worn. The confusion is greatly relieved and objects are quite distinct. Theatre curtains stand straight with a

possible slight distortion in the upper left. That is, it pitches upward. Generally everything seems normal."

A recheck on the space eikonometer with the patient wearing the refractive prescription, the fitover, and prisms: $\times 90$: L 0.2 percent ± 0.3 degrees; $\times 180$: 0.0 percent ± 0.4 degrees; δ : 0.0 ± 0.4 degrees. The space-eikonometer test without aniseikonic fitovers showed: $\times 90$: 0.0 percent ± 0.3 degrees; $\times 180$: 0.0 percent ± 0.4 degrees; δ : -1.1 ± 0.4 degrees.

On September 28, 1943, he was given 2-percent meridional aniseikonic fitovers converging down, which he wore with comfort until July 6, 1944, when he received permanent spectacles of the same prescription.

On November 6, 1946, however, the patient returned because of a recurrence of black specks and a burning feeling in the eyes. He had also suffered some frontal headache for a few months. His general health had been excellent. On examination, the eyes were externally normal, pupils normal. Slitlamp examination showed a small nuclear dot in the lens of the left eye, with visible vitreous strands. In the right eye there was a wavy band of tissue attached at the disc and floating in the vitreous which came only slightly forward.

Subjective refraction was: R.E., with a -1.00 D. sph. \ominus -3.25 D. cyl. ax. 165° , 20/30; L.E., with a -1.25 D. sph. \ominus -3.50 D. cyl. ax. 20° , 20/30. Motility with old aniseikonic glasses of July 6, 1944 was: Distance: Eso. 1 to 2, L.H. 2 (prism diopters); Near: Eso. 2, L.H. 2. Fusional amplitudes were: Distance: Convergence, 12/9 (break, recover); divergence, 8/6; vertical divergence, $+2/1$ (base down right), $-3/2$ (base up right). Near: Convergence, 11/9; divergence, 10/8. The near point of convergence was 7 cm. Stereopsis was 100 percent on the Keystone DB6 card. The right hand and right eye were dominant. The space-

eikonometer test with old aniseikonic spectacles of July 6, 1944, showed: $\times 90$: L 0.9 percent ± 0.3 degrees; $\times 180$: L 0.4 percent ± 0.4 degrees; δ : $+0.3 \pm 0.2$ degrees. The space-eikonometer test with new refractive prescription in trial-case lenses was: $\times 90$: L 0.8 percent $+0.3$ degrees; $\times 180$: L 0.4 percent ± 0.4 degrees; δ : -1.2 ± 0.2 degrees.

SUMMARY

A 24-year-old bank clerk with disability due to severe eye strain was not relieved after two years of treatment with refractive prescriptions with or without prisms to correct the hyperphoria present. He wore the same refractive and prismatic correction with the addition of aniseikonic correction for three years with marked subjective relief of eye strain, and marked improvement of stereopsis, as measured by the Keystone DB6 card, and by sensitivity when measured on the string target of the space eikonometer. His old difficulty in focusing on any small object, especially one in motion, disappeared.

Although he left his position in the bank because of his eyes, he returned to it when he got his aniseikonic correction. His employer told us that his work was incomparably more efficient since he had worn these glasses. The recent change was small, and involved only the cylindrical correction. The measured oblique aniseikonia had not changed.

Unfortunately, the diplopia fields were not repeated with aniseikonic glasses on. However, the aniseikonic addition to the the prescription has always been symmetrical over the two eyes, and would therefore induce a change in anisophoria only by decreasing the exocyclophoria present. It is possible that this decrease in cyclophoria is as important as the effect of changing the image shape in oblique aniseikonia.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

February 10, 1947

DR. J. B. STANFORD, *presiding*

RECESSION OF INFERIOR RECTUS

DR. JAMES E. WILSON reported that R. W., a youth, aged 19 years, was seen July 15, 1946. Five months previously he had received a head injury. Upon recovery the only residual symptom was diplopia. After one month's observation, the diplopia persisted in the same degree.

Vision was 20/20 in each eye, and the refractive error was negligible. Except for defective ocular motility the examination of his eyes was normal. Ocular rotations were full in all directions for the right eye but were definitely limited downward and to the right for the left eye. While the right eye fixed, the left eye was up and to the left. Diplopia fields showed that separation increased upon looking downward. While looking downward, separation was greater to the right than to the left. Image tilting and lateral separation also supported the diagnosis of paresis of the left superior oblique. Left hypertropia was measured at 10 prism diopters for distance and 15 prism diopters for near.

At operation five months after injury, a 5-mm. recession was performed on the right inferior rectus. Immediately post-operatively, there was a considerable over-correction. Two months following the operation, there was $\frac{1}{2}$ prism diopter of right hyperphoria at 20 ft. and $\frac{3}{4}$ prism diopter of left hyperphoria at 13 inches. The patient could read with comfort. There was single binocular vision in all fields except when looking extremely

down and to the right. Diplopia fields showed superimposition in all fields except when the light was carried extremely downward and to the right.

CICATRIX OF EYELIDS

DR. J. WITHERS by invitation reported that his patient M. L. C., a colored girl, aged 11 years, had spilled lye in her left eye when about two years of age and had received no treatment until first seen in the Clinic on June 28, 1946, complaining of an unsightly and tearing left eye.

She was found to have contracture of both lids of the left eye, with an extensive ectropion of the upper lid and no conjunctival sac inferiorly. The eye was a small degenerated calcareous mass whose cornea had been replaced by a matrix of veins. The lacrimal puncta were lost in the cicatrix, and there was severe epiphora with low-grade infection of the area.

On August 1, 1946, enucleation of the degenerated left eye and implantation of a glass ball were performed. On September 4, 1946, a skin graft from behind the left ear was placed in a spread incision of the lower lid, and a skin graft from the right upper lid was placed in a spread incision of the left upper lid. Adhesions of the subcutaneous tissue were cut and the ectropion was reduced and held in place by catgut sutures anchored high in the upper lid. A small mucous-membrane graft from the lower lid was placed in the new inferior conjunctival sac. A small wax conformer was placed in the conjunctival sac and two padded mattress sutures were placed to hold the lids together.

This case was presented in an effort to determine what future operations could be done to correct the epiphora and the absence of eyelashes.

ANOMALIES OF OPTIC DISC

DR. PHILIP MERIWETHER LEWIS presented two patients having very unusual nerve heads.

Case 1. V. B., a white man, aged 38 years, had no ocular symptoms except those due to a mixed astigmatism of his right eye for which he wore glasses. He was seen for a routine refraction. The vision was 20/20 in each eye. Both eyes were normal externally and the fundi normal except for the optic disc of the left eye. The disc was larger than normal with its horizontal diameter slightly greater than the vertical. At the temporal border, there was an oval-shaped, bluish-gray area, which was sharply demarcated from the rest of the disc. The patient stated that when his eyes were examined 10 years ago that the peculiar appearance of the disc was discovered. There was a moderate enlargement of the blindspot horizontally. The field was normal.

Case 2. J. B., a white man, aged 31 years, was first seen for refraction in April, 1942. He thought the vision of his left eye had been poor for many years, but he had never been examined before. The eyes were normal except for the left disc. A yellowish mass extended from the upper border temporally to just above the macula. It was quite large being about $2\frac{1}{2}$ times the size of the disc. Its surface had an irregular or shingled appearance. Corrected vision, in 1942 and in 1944, was 20/30, but it was only 20/50, in 1946. The refractive error (+1.75D. cyl. ax. 45°) had remained the same. It seemed that the growth was larger than in 1942, but unfortunately photographs were not made until recently. A very large absolute scotoma extended from the normal blind spot downward to the 90-degree meridian. The peripheral fields for form and color were normal. Fundus photographs made in August, 1946, were shown.

FOREIGN BODIES OF EYE

DR. PHILIP MERIWETHER LEWIS reported six recent cases of penetrating wounds of eyes with steel particles.

Case 1. E. H., a white man, aged 28 years, was pounding with a hammer while repairing some farm machinery when something struck his left eye. He was seen two days later on August 5, 1946, because his eye was getting sore. There was a small wound of the limbus at the 7-o'clock position with a small hole through the base of the iris. There was considerable ciliary congestion and the aqueous was a little hazy, but the fundus was normal. Vision was reduced to 20/200. X-ray pictures by Dr. Daniel Fisher showed the steel in the ciliary body just peripheral to the limbal wound. It was necessary to enlarge the wound after which the steel was removed by application of a hand magnet. It measured 4 by 2 by 1 mm. Six hundred thousand units of penicillin were given postoperatively together with one milk injection. The patient resumed work three weeks after the injury with his eye entirely quiet and vision of 20/40. The lens was clear.

Case 2. R. M., a white man, aged 30 years, was cutting concrete with a hammer and chisel on August 17, 1946, when something struck his left eye. He was seen about four hours later. There was a wound through the cornea at the 6-o'clock position and a hole through the base of the iris. The iris was congested and the pupil very small. Vision was reduced to counting fingers at three feet. X-ray pictures by Dr. D. H. Anthony showed the steel to be in the orbit below, outside of the globe. After the pupil was dilated a hole was discovered in the midline below, about 4 to 5 disc diameters below the macula. The hole was white in color, elliptical in shape and about $\frac{3}{4}$ mm. long. About nine hours after the injury, surface diathermy was

applied to the area of the scleral wound after cutting the inferior rectus from its insertion to secure proper exposure. Considerable iritis developed which subsided promptly under treatment with penicillin, milk injections, atropine, and neosynephrin. Three weeks later pigmented spots were seen all around the site of the wound. No detachment occurred, but vision was only 20/50. The lens was clear.

Case 3. C. C., a white man, aged 24 years, was using a hammer to repair a mower on August 31, 1946, when a piece of steel struck his left eye. The steel entered through the sclera at the site of the insertion of the internal rectus, but was located 16-mm. posterior to the apex of the cornea and 9-mm. lateral to the midline. Vitreous was protruding from a rather large wound, the eye was very painful and greatly swollen. Application of the giant magnet elicited no response, but on introducing the magnetic tip of a squint hook through the wound, the steel was readily removed. It measured 4 by 3 by 1.5 mm. Diathermy was applied to the sclera and to the wound. Over a million units of penicillin, foreign-protein injections, and sulfadiazine administered orally failed to prevent the development of panophthalmitis. Evisceration on the seventh day after injury was followed by prompt recovery.

Case 4. H. H., a white boy, aged six years, was watching his mother repair a chicken coop on August 24, 1946, when something struck his left eye. There was a large prolapse of iris through a penetrating wound of the cornea at the limbus, laterally. Vision was reduced to light perception. X-ray pictures showed a metallic foreign body either in the orbit or in the posterior part of the globe. The child would not permit accurate localization. Application of the giant magnet gave no result. An iridectomy was performed. Vision had improved slightly (5/200),

but the vitreous was so hazy that the fundus could not be seen.

Case 5. B. P., a white boy, aged two years, was playing in his father's blacksmith shop on August 30, 1946, when a piece of steel struck his left eye. The tip of the steel penetrated into the anterior chamber, but it remained lodged deep in the cornea. The steel was removed by magnet extraction in another city, and the eye did well for five days. It then became violently inflamed and the child was brought to Memphis. A dirty gray wound, surrounded by very hazy tissue, could be seen through the cornea in the lower pupillary area. The aqueous was cloudy, and there was marked ciliary congestion. The wound was scraped out causing the aqueous to escape. The infection was brought under control by means of foreign-protein and penicillin injections plus the usual local treatment.

Case 6. J. M., a white man, aged 53 years, was seen on September 10, 1946. About four years previously he remembered on two occasions having steel removed from his left cornea, but he could not recall how the injuries occurred. An intraocular foreign body was evidently not suspected. About a year ago the vision began to fail, but not until five days previously did the eye become red and painful.

There was a hole through the iris. Siderosis bulbi was present, the iris being a rusty yellow color instead of blue, which was the color of the other eye. A low-grade iritis was present with dense posterior synechiae which could be only partially broken with the most powerful dilators. Vision was reduced to 10/200. X-ray pictures by Dr. D. H. Anthony showed no trace of any foreign body. Evidently the metal had become completely dissolved by oxidation. Hospitalization for treatment with foreign proteins was advised, but refused.

GONIOTOMY FOR GLAUCOMA

DR. J. WESLEY MCKINNEY reported two cases of congenital glaucoma in which goniotomies were performed.

Case 1. W. M., aged seven months, was seen in August, 1945. The baby had had a trephination of each eye for congenital glaucoma three months previously. Notes made at that time stated that both corneas were large, and tension was 35 mm. Hg (Schiotz) in each eye. The fundi were not seen. The tension had remained normal for a while and was now up again, and the corneas were slightly steamy. On August 25, 1945, under ether anesthesia, the tension was 30 mm. in each eye. Goniotomy was performed on both eyes. About one third of the corneoscleral trabeculum in its nasal portion was cut with the goniotomy knife. The postoperative course was uneventful. On September 12th, tension was again up. Under vinethane anesthesia, it measured 35 mm. in the right eye and 40 mm. in the left. Eserine was used for a while but was soon stopped as the eyes seemed all right. The child, now 13 months of age, was last seen February 20, 1946. The parents stated that the child seemed to see very well. The corneas were clear and the tension was unquestionably normal to fingers.

Case 2. D. M. G., aged three months, was seen in May, 1943. At birth a diagnosis of interstitial keratitis of the left eye had been made, presumably because of the steaminess of the cornea. Examination revealed the left cornea to be large and somewhat steamy. There was a horizontal band of superficial nebulous opacity across the center of the cornea. The right eye seemed normal. Under ether anesthesia, the fundi were poorly seen with a -18 lens in each eye and appeared normal. The tension was 20 mm. Hg (Schiotz) in the right eye and 45 mm. in the left. A goniotomy was performed

cutting the corneoscleral trabeculum from the 3-o'clock to about the 11-o'clock positions. The postoperative course was uneventful. Two-and-one-half years later the tension remained normal.

THREE CASES OF "SOFT GLAUCOMA"

DR. E. C. ELLETT said that some report of this condition has been made now and then since 1924, and that Dr. Arnold Knapp's report of 10 cases, in 1932, called attention again to the condition and its association with sclerosis of the cerebral basal vessels. All cases present some impairment of vision and visual fields, optic atrophy with marginal or complete excavation of the disc, and possible radiographic evidence of calcification of the cerebral basal vessels. The intraocular pressure is not increased. The vessels affected are generally the internal carotid, ophthalmic, and the posterior communicating, but the changes are always slight and often cannot be shown by X-ray.

Operation is not indicated, and no treatment seems to help, although all cases do not progress. Dr. Ellett operated on one of his patients because the patient had been advised to have an operation by a very good ophthalmologist, and Dr. Ellett was afraid not to give him the benefit of the operation. The patient's trouble has not progressed in the 3½ years since the operation. The other patients have used miotics and have been treated with general tonics.

The last report on this condition Dr. Ellett has seen was one by MacLean and Ray to the Section on Ophthalmology of the New York Academy of Medicine in April, 1946. This was the report of a case, which has not yet been printed. He has borrowed from them the name of "soft glaucoma," which is not a good name, because everybody agrees that the condition is not glaucoma. Dr. Knapp dis-

cussed this report and is still of the opinion that the trouble is optic atrophy associated with sclerosis of the basal arteries. He spoke of the altitudinal field defect, which is characteristic, but not always present, the cupping of the disc, and the low tension. He said that the calcification of the basal vessels is not always visible to the X ray. No new suggestions were made as to treatment.

Case 1. C. D., a man, aged 68 years, was seen in January, 1944. Vision in the right eye had been blurred for a year and was getting worse. There were no other symptoms. Vision was 6/18 corrected to 6/6. The right eye had a 4-mm., slightly active pupil. There were a few lens and vitreous opacities; the nerve was white and slightly cupped. In the left eye, the media were clear; the nerve was less cupped and of better color. Tension was 20 mm. Hg (Schiotz) in each eye. The only change in nearly three years was in the fields. The tension once went to 28 and 30 mm., but has usually been 18 and 20 mm. Vision at present was 6/20 and 6/7.5+, with glasses. Dr. Arnold Knapp has kindly seen this patient several times. In June, 1944, he wrote: "I dilated his pupils with neosynephrin and found in both optic nerves: scleral ring, shallow depression, atrophy right marginal cup above. The case does not impress me as one of glaucoma but as that type of optic atrophy with shallow excavation which is probably due to interference in nutrition of the optic nerves." As the field was not taken at first on the tangent screen, the arcuate scotoma was not found. The treatment has been pilocarpine, no smoking, and a general tonic. Dr. Knapp has recently seen this patient. No X-ray studies have been made of the intracranial vessels.

Case 2. P. R., a man, aged 60 years, was first seen in 1943. Glaucoma had been diagnosed two years before. Vision in each eye was 6/6 and J1, with glasses.

Tension was 18 mm. Hg (Schiotz). Blood pressure was 175/125 mm. Hg. The patient was diabetic and was on diet. The discs in both eyes were definitely cupped. He had seen several doctors, some of whom advised operation and some of whom did not. An iridencleisis was done on both eyes in April, 1943. In October, 1946, vision was 6/7.5 and 6/6 and J1 with each eye. Tension was 13 mm. and 20 mm.

Case 3. D. H., a man aged 59 years, was seen in 1941, complaining of blurred vision especially for near for two years. He had a diagnosis of glaucoma and was using drops. The eyes were normal externally. The pupils measured 3 mm. and were active, especially the right. Vision was: O.D., 6/6 with a +2.00D. sph., and J1 with a +4.50D. sph.; O.S., 6/24, with glasses, and J20. The right fundus was normal. The left nerve was cupped in the outer half, but a crescent of good nerve persisted nasally. The vessels dipped above and below. Tension was 26 mm. Hg (Schiotz) in both eyes. Blood pressure was 118/80 mm. Hg. Fields were: O.D., normal; O.S., an arcuate scotoma above the fixation point. There was apparently some calcium deposit in the central vessels. After five years, the right eye was still normal with vision of 6/7.5 and J1 with glasses. Vision in the left eye was 6/30, but better for near. Tension was still normal. The patient was still using pilocarpine three times daily.

Daniel F. Fisher,
*Recorder for the
Eye Section*

SOCIEDAD OFTALMOLOGICA DE MADRID

December 20, 1946

DR. CORTEZO, *presiding*

The inaugural session of the term

1946-47, celebrated on December 20, 1946, was presided over by the Inspector of Health, Dr. Cortezo, representing the Director General of Health. On the platform were the president of the society, Dr. Martin Amat; the secretary, Dr. Mier; the vice president, Professor Carreras; and Dr. Mario Esteban who had charge of the inaugural lectures.

After a few brief words by Dr. Marin Amat, Dr. Mier, outlined the work which was accomplished during the previous term. He commented on the current progress and paid tribute to the memory of the departed Dr. Garcia Miranda.

HISTORY OF OPHTHALMOLOGY

DR. MARIO ESTEBAN gave the inaugural lecture. His paper was on "Past, Present, and Future of Ophthalmology." Dr. Esteban commented on the superstitious practices with which diseases of the eye were ostensibly cured in primitive times by primitive peoples, practices very similar to those which can still be observed among some tribes far removed from civilization.

The Hellenic genius showed itself in the art of curing the eyes, as in all activities. In Rome, medicine was in a low state until it received the influx of Greek culture. Tablets and seals and instruments of the oculists from the Roman Empire are still to be found in Spain.

When the Empire of the Caesars began to fall apart because of the vice and corruption of the times, there arose in sharp contrast, the sublime figure of Jesus of Nazareth. He preached virtue and taught us by His example that to cure the sick and to restore vision to the blind is a divine gift. In order to deserve it and to enjoy it we must always try to attain intellectual and moral perfection. At the fall of Imperial Rome the Arabs salvaged a culture which was about to perish. The Arabian doctors showed a strong pre-

dilection for ophthalmology, the study and practice of which were rigorously regulated.

During the middle ages, ophthalmology found shelter in the monasteries. It is well worth mentioning that during this period lived our compatriot, Pietro Hispano, Pope Juan XXI, who was an oculist and author of a work on ophthalmology.

At the coming of the renaissance, science, literature, and art were released from the classical molds of Greece and ancient Rome. Leonardo da Vinci, anatomist, artist, and creator of scientific theories, stands as a symbolic figure. During the 17th, 18th, and 19th centuries, there were continuous studies and discoveries among which the discovery of the ophthalmoscope marks a new era in the progress of ophthalmology.

At present, after 5,000 years of accumulated knowledge, ophthalmology is an extensive and profound science, but still in the stage of development. We cannot foresee the future of ophthalmology except as we can visualize it in our imagination. First there will be a period during which surgery will dominate, with bold operations in order to repair blind eyes as if they were a mechanical apparatus in which a piece has to be replaced.

At the same time there will be great advances in knowledge about diseases like cataract and glaucoma. These diseases will no longer need surgical treatment because it will be possible to prevent them and cure them by medical means. The oculists of the future centuries will read with curiosity and not without admiration the technical practices of their colleagues of the 20th century. In the future there will be experiments as a result of which the blind will be able to receive impressions of light and color. It will be possible to convert light stimuli from the

outside into photoelectrical energy which will be transmitted to the brain by other channels than the retina. This perhaps will be less spectacular than applying atomic energy to kill and destroy, but it will nevertheless be much more beautiful.

RECEIVES HEALTH DEPARTMENT AWARD

DR. DON FERMIN GALINDEZ IGLESIAS was awarded the prize of the General Department of Health. The prize of the Ophthalmological Society was declared vacant, and the president, Dr. Marin Amat, stated that it will be added to that of the term which was beginning. Finally, Dr. Cortezo, in the name and as a representative of the General Department of Health offered his congratulations to the Ophthalmological Society of Madrid for its contributions to the public welfare.

Joseph I. Pascal,
Translator.

BROOKLYN OPHTHALMOLOGICAL SOCIETY

December 19, 1946

CAMPIMETRY WITH ULTRAVIOLET LIGHT

DR. GEORGES KLEEFELD demonstrated the technique of campimetry with ultraviolet light. The theory of using luminous paint for fixation was discussed. It appears that the normals of measurement in campimetry with this technique are identical with those of the usual manner of examination. No harmful effects are attributed to the procedure according to Dr. Kleefeld. The suggested advantage is ease of visual response by the patient.

FUNDUS CHANGES IN VASCULAR DISEASES

DR. HERMAN ELWYN presented in detail the histopathologic background of:
(1) The physiologic aging process. (2)

Arteriosclerosis. (3) Essential hypertension, benign and malignant. (4) Renal hypertension, with particular emphasis on ophthalmoscopic appearances.

ANIRIDIA CONGENITA

DR. MORRIS PINCUS presented five patients with bilateral aniridia, including the genealogy and treatment possibilities. The clinical and pathologic features are furrowed brow, narrow palpebral fissures, unusually large pupils, photophobia, poor vision, and frequently nystagmus. The apparent absence of the iris on clinical examination is due to the fact that a short stump is hidden behind the corneoscleral margin. Other ocular defects such as ptosis, muscular imbalance, corneal disturbances, lenticular anomalies, and pathologic condition of the retina are quite common. Glaucoma, as a secondary complication, is not uncommon. Several useful procedures of treatment are available. Tattooing of the outer portions of the cornea, extraction of a cataractous lens, and the wearing of an opaque contact lens, with a 3- to 4-mm., clear, central pupil, are the methods of choice. Glaucoma, as a secondary complication, can be controlled by eserine or a corneoscleral trephination.

George A. Graham,
Associate Secretary-Treasurer.

WILLIAM A. MANN, *president*

CLINICAL PROGRAM

The clinical program was presented by the Department of Ophthalmology, University of Illinois.

HEMANGIOMATA OF PALPEBRAL CONJUNCTIVA

DR. M. R. FOLK presented V. H., a girl, aged 9½ months, whose parents noticed an enlarged upper left lid at birth. The family and past histories were negative except that the child was jaundiced for one month after birth.

Examination showed a smooth swelling of the left upper lid, causing complete ptosis. The swelling was more marked at the lateral aspect. The left eyeball seemed to be slightly proptosed and had a convergence of 20 degrees. There was no evidence of an inflammatory process. Palpebral and fornix conjunctiva was three times the normal size and when inverted covered the entire eye. The pupils reacted to light and accommodation and dilated evenly to 7 mm. Both discs showed normal color and arrangement of vessels. X-ray pictures of the orbit showed no demonstrable pathologic condition. Physical and laboratory findings were normal.

The patient received eight 150r X-ray treatments applied to the lateral orbital area through a field cone, following which there was some regression of the condition. No further treatment was given for one month. No further regression occurred, and the patient was again admitted to the hospital. Sodium morrhuate was then injected into the area of lesion of the left tumor and, as a result, a 2-mm. slitlike opening, not present before, was seen nasally.

VON HIPPEL-LANDAU'S DISEASE

DR. M. R. FOLK said that M. D., a 25-year-old white woman, complained of pain in the left eye and headache in the temporal region, worse after prolonged use of the eyes. There had been progressive loss of vision in the left eye in the past three months. At the age of 14 years, the patient had had poliomyelitis, from

which she recovered after six months. At the age of 19 years, she developed left hemiparesis, was hospitalized for one week, but could not walk for two months thereafter. Three years ago she had had an attack of headache, vomiting, blurred vision, and grand-mal convulsions, and has had two more convulsive seizures since then.

A neurologic diagnosis included organic brain disease, residue of left spastic hemiparesis complicated by epileptiform seizures. Arteriograms of the left carotid showed an anterior cerebellar artery filling from the left side. It appeared likely that the symptoms resulted from a cranial aneurysm similar to those found in the retina.

Vision was R.E., 1.2; L.E., 10/200. The left eye had a tendency to deviate outward but was able to maintain parallelism. The ocular movements were normal. The iris was normal. The pupils, 4 mm. in diameter, reacted to light and accommodation. The right fundus was normal. The left fundus showed the disc to be pale temporally, the margins clearly outlined, with normal arrangement of blood vessels. In the macular region a star-shaped exudate was seen. Many discrete and confluent patches near the periphery extended from the 2- to the 6-o'clock position. Beyond the macula the inferior branch of the superior temporal artery was covered by a reddish yellow lesion, 2 to 3 disc diameters in size, surrounded by a circle of flame-shaped hemorrhage. Many small saclike aneurysmal dilations were noted in the same area. The fields showed a central scotoma. Tension was normal.

MACULAR AND CHOROIDAL DEGENERATION

DR. STEPHEN W. SUKUMLYN presented E. C., a white man aged 53 years, who complained of photophobia, lacrimation, and loss of vision in both eyes for

12 years. He had been employed as a moulder, handling liquid metal, for five years.

There was a divergence of the left eye of about 20 degrees; otherwise the external findings were normal. The pupils reacted to light and accommodation. The visual acuity in both eyes was reduced to counting fingers at two feet. After homatropine retinoscopy, vision could be corrected to 10/200 in both eyes. With the ophthalmoscope, the disc of the right fundus was seen to be orange-yellow in color and the small, cupping disc margins to be hazy. The vessels were attenuated throughout their course in the ratio of 2 to 1. The central areas of both fundi were involved by large plaquelike lesions, somewhat depressed, having an irregular margin angulated at several points, with moderate disturbance of pigment along the edges. The bases of the lesions were pinkish red in color and appeared to be crossed and recrossed by a fine capillary network. The periphery of each fundus, at frequent intervals, was stippled with fine pinhead spots where the pigment migrated into the inner layer of the retina. In the right eye, above and temporally, was a pigmented threadlike structure occupying the upper outer quadrant. Otherwise the findings of the left eye were almost the same as those of the right.

Fields showed a large central scotoma, breaking through on the nasal side. Fields were taken with the 10-mm. target for white only; other colors were not recognized.

All physical and laboratory tests were within normal limits. From the history of long exposure to light of high intensity, it is possible that this might be a factor in the cause of the present findings.

GYRATE ATROPHY OF CHOROID AND RETINA

DR. STEPHEN W. SUKUMLYN said that

A. S., a white woman aged 66 years, complained of substernal pain, dizziness, and loss of vision in both eyes, with night blindness. The eye symptoms were of two years duration. There was no history of eye disease in the family.

External examination showed a large nevoid, brawny growth on the left eyebrow. Vision was: R.E., 0.6; L.E., 0.4; and could not be improved. Examination of the fundi through dilated pupils showed the lenses to be clear and the discs to be lemon-yellow in color. The margins on the nasal sides were frayed, the surfaces not elevated. Cupplings of the discs were small, deep, and centrally placed. Retinal vessels were much attenuated in the ratio of 2 to 1. In the periphery were fine threads. In the region of the disc and macula, an area of normal fundus was surrounded by a ring of atrophy, which in the periphery of the fundus was of scleral whiteness, with almost complete absence of choroidal and retinal vessels. As the ring of atrophy encroached on the central region of the fundus, the faint outlines resembled a crumbled framework of tongues, circles, and ovals, the contours being very distinct on the border of normal fundus. The condition was more advanced in the left eye.

Fields taken with the 3-mm. white target were contracted to between 15 and 10 degrees, in both eyes. The blood pressure was reported to be 240/140 mm. Hg. The dermatology department reported pityriasis rosea. Complete laboratory and physical examinations gave negative results otherwise.

The patient's eyes were dilated on several occasions, and in spite of the use of myotics after dilation, an acute bilateral glaucoma supervened for which operation was performed.

Twenty-six cases of gyrate atrophy of the choroid and retina have been reported in the literature between 1888 and 1932,

including one by Fuchs in 1895. He discussed this case in detail and gave it the term of gyrate atrophy of the choroid.

SCIENTIFIC PROGRAM

The Cover Test, presented by Dr. Hilmer Martin (by invitation).

Anomalous Correspondence, by Dr. Beulah Cushman.

A Therapeutic Routine in Cases of Strabismus, presented by Dr. John Hitz (by invitation).

Richard C. Gamble,
Secretary.

COLORADO OPHTHALMOLOGICAL SOCIETY

November 16, 1946

DR. JOHN C. LONG, *presiding*

RETROLENTAL FIBROPLASIA

DR. HUGH KINGERY (by invitation), as a preliminary to the discussion of retrolental fibroplasia, outlined the embryology of the vitreous. He explained that this body is not histologically a tissue but is a secretion of many of the ectodermal and mesodermal contiguous structures. The primary vitreous is deposited immediately behind the lens body and there remains, becoming surrounded by the secondary and tertiary vitreous bodies. The generous blood supply of this primary vitreous comes from the central artery and normally degenerates along with the rest of the hyaloid arterial system.

DR. RALPH W. DANIELSON presented a paper on what the late Dr. T. L. Terry called retrolental fibroplasia and on what Dr. A. B. Reese has designated as persistence of primary vitreous. This material was generously furnished him personally by these authorities. The essential pathology of the condition is a persistence of some part of the tunica vasculosa lentis, a hyperplasia of this tissue, and a hyperplasia of the fibrillar structure of the embryonic primary vitreous. It must be differentiated from retinoblastoma and various other forms of pseudoretinoblastoma. He reported seven such cases seen in Denver and described an attempted biopsy made on one. The collapse of the globe from loss of fluid helped to prove the case to be other than one of a glioma. No treatment has been very successful; prophylaxis seems to offer the only hope. A variety of methods for examination for differential diagnosis was outlined.

Discussion. Dr. Harry Gordon (by invitation) said that there was no question of this condition being associated with premature births. Since five percent of all births are premature and since more and more of these babies will be saved, more cases of this disease will be seen.

Dr. Danielson, in closing, suggested that all these babies be examined under general anesthesia and that a fixation forceps be used to move the eye. The mydriatic of choice would be $\frac{1}{4}$ -percent homatropine.

Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 700 North Michigan Avenue, Chicago 11, Illinois; Society Proceedings to *Mrs. Katherine F. Chalkley*, Lake Geneva, Wisconsin. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 700 North Michigan Avenue, Chicago 11, Illinois. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, *Mrs. Katherine F. Chalkley*, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Alnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

PERIMETRY

According to the findings of the American Board of Ophthalmology, one of the subjects in which the candidates for the certificate are most weak is perimetry. This soft spot in the training of an otherwise well-rounded ophthalmic candidate includes not only the theoretical but, what is more surprising, the practical aspects of the subject as well. The majority of can-

didates showed themselves to be especially poorly grounded in the technique of taking a peripheral field. In the practical examination, many paid no attention to the important points of seating the patient properly, or of making him comfortable, or of instructing him as to what was expected of him, and so on. Many of the candidates had been in practice for a number of years. A number confessed to

the possession of poor pieces of apparatus; some were content with a hand perimeter, and not many had any form of central-field apparatus. Illumination, the size of the test objects, and distance from the screen seemed to be of little importance to them.

The taking of visual fields began with Thomas Young, in 1801, and was later elaborated by Purkinje, in 1825. Von Graefe, in 1855, and Aubert and Förster, in 1857, used perimetric studies of the gross defects in the field of vision diagnostically, but it remained for Bjerrum, in 1889, to develop a method for the accurate taking of the central fields which led to the invention of the Bjerrum screen. Thanks to the profound studies and analyses of Roenne, Sinclair, Traquair, Walker, Peter, and many others, we are in a position today to profit by the study of visual fields of our patients in a measure unheard of 40 years ago.

The interpretation of a visual-field defect is thus almost an exact science. The taking of a visual field remains, and always will remain, an art. As Duke-Elder has so ably said: "Its essential drawback is its subjective nature, for the examiner is always dependent upon the mentality and coöperation of the examinee, and the difficulties with the unintelligent patient who does not coöperate are almost insuperable. To these physical characteristics, which cannot be controlled and are difficult to estimate, must be added the personality of the examiner himself, as well as physical considerations, such as the size of the pupil, the condition of the refractive media, the illumination, and a host of other factors. It is essential, therefore, that in any method employed, simplicity should be the keynote, and the complexity of the apparatus or overdue attention to minute detail in technique should never be allowed to govern the interpretation of the results."

The neurologist or neurosurgeon, despairing of getting a good and fairly accurate perimetric study of his patients from his ophthalmologic colleague, has, beginning with Cushing, tended to rely more and more upon himself in this matter. However, judging from a perusal of perimetric charts made by the average neurologic resident, the ophthalmic house officer still has a slight edge on his neurologic colleague in this affair. This gives us small comfort, for the work of neither in this line is completely satisfactory.

It is entirely up to us to develop our interest, technique, and skill in perimetry to the point where we excel in this endeavor and are able to convince our neurologic colleagues that only we are capable of making proper perimetric and campimetric studies and that we are on a par with them in the matter of interpretation of the defects uncovered.

How has it happened that we have slipped and are slipping in a vitally important and significant diagnostic test? What accounts for the poor showing of our candidates? The answers to these questions are no doubt complex, but probably lie in the fact that we are too busy doing other things with our patients to bother with a tedious, time-consuming, and often irritating test, regardless of its importance. Thus it happens that many, if not most, of our top-flight ophthalmologists are satisfied with either a rough confrontation test or delegate the perimetric studies to an office assistant, who frequently is a lay person. This, of itself, is not bad provided the technician is thoroughly trained in the art of taking peripheral and central fields, although no one can do it as well as the ophthalmologist himself. The evil arises in the fact that these busy ophthalmologists of skill and renown are often teachers of ophthalmology in our schools and hospitals,

or are the preceptors of the young ophthalmologist. Having given up for many years the taking of fields of vision themselves, they are not interested and are usually very rusty in matters of the technique and the art. They, therefore, are not fit to instruct the young except in the interpretation of the findings.

The solution of this difficulty lies in the awareness on the part of the staff of the department of ophthalmology in our schools and especially in our hospitals of our failure in this field and then the correction of this failure by placing proper emphasis on instruction courses in perimetry. There is generally some member of the staff of every institution who is not only interested in perimetry but who is often an enthusiast. He should be encouraged and supported by designating him the instructor and by giving him the facilities and the responsibility not only for training the student in this difficult art but also for pointing out to him its great clinical significance.

It would seem that modern methods of visual education are particularly well suited to teaching this subject. Training films, sponsored by the Academy of Ophthalmology and Otolaryngology, would be of the greatest value to the teacher and student alike. It is the duty of every department of ophthalmology to conduct a stimulating and satisfactory course in perimetry—a course open not only to the residents and postgraduate students but also to practicing ophthalmologists who feel the need for such a course.

Judging from the poor quality of perimetry performed by the average practicing ophthalmologist and particularly by those who do ear, nose, and throat work in addition, as shown by the records of the Board, such a course is urgently needed in all parts of our country.

Derrick Vail.

FASHION AND SPECTACLES

It is hardly surprising that spectacle lenses and frames are subject to the same sort of vagaries as other articles of dress. The variations are by no means always made for the benefit of the patient, although often at his expressed desire, whether for the purpose of imitating his friends and neighbors, or because he is told by the counter optician that "this is the latest style."

It is a far cry from the bifocal combination which Benjamin Franklin ordered of his Paris optician to the various types of invisible bifocals of today. On the whole it is probable that the great Philadelphian was at least as comfortable in his split bifocals as the citizen of today in his more or less invisible and much more expensive one-piece lenses. But no one cares to make himself conspicuous with the type of lenses worn by Benjamin.

Nothing perhaps is more conspicuous in school children of the modern United States than the desire to be conspicuous, and quite in harmony with this tendency, if with nothing else, is the fad for eccentric shapes in spectacle frames, particularly the use by girls of a type of plastic frame which somehow suggests a pair of cow horns.

The spirit of Henry Ford appears to have taken hold of the industry of manufacturing spectacle frames, at least so far as quantity production is concerned. Although for some people the use of side pads may represent a great improvement over the old-fashioned saddle bridge, there are a good many forms of facial architecture for which the saddle bridge is vastly preferable. Yet today it is almost impossible to obtain the saddle-bridge frame. The completeness of the change indicates a lamentable lack of consideration for public interest as against profit-making.

It is refreshing to see that some of these modern trends in the wholesale optical industry can arouse scruples in the minds of optical dispensers. Mr. William Frank Davis, of the firm of John Wooster and Company, San Francisco, under the title "Remember the Oxford?" asks in *Guildcraft* (organ of the Guild of Prescription Opticians of America, February-March, 1947, page 28) the following questions: "What has happened to the theory that a pair of glasses should be made as inconspicuous as possible on the patient's face?" "What has happened to the theory that in fitting a spectacle frame balance is achieved in the correct fitting of the bridge, and not in attempting to hold the lenses in position by temple tension?" "What has happened to the theory that lens size is controlled not only by the difference between the pupillary distance and the distance between lenses, but by the conscious idea of form and appearance, so that the patient will not have the appearance of an owl?"

We may further ask how much has been gained by the tendency toward use of very large lenses, much larger than would be indicated by the patient's pupillary distance. As a matter of personal comfort, it would be much more satisfactory to use small lenses, because increase in the weight of spectacle lenses develops almost in geometric proportion to the diameter of the lens. When, a few years ago, some of the more conservative and independent among us ventured to criticize this tendency to large lenses, we were assured that its aim was to give the patient a larger field of vision. It was fruitless to point out that the ordinary habits and purposes of vision utilize only 10 or 15 degrees at the center of the lens. Today we are urged to have our aphakic or high hyperopic or myopic patients wear

"lenticulars," in which not more than one half of the total area of the lens is ground to prescription, the remainder of the piece of glass being entirely without value from the optical point of view. How much more comfortable many of these patients would be, without any loss of visual efficiency, with the antique type of small lens! Mr. Davis is certainly correct in maintaining "that we still have a responsibility to the eye physician and the patient." "We cannot ride," he adds, "on style and style alone."

The tendency to sacrifice efficiency to style (largely imposed by manufacturers) renders it more frequently difficult for the ophthalmologist (or optometrist) to be certain that the pair of spectacles delivered to the patient will correspond exactly with the prescription formula. The larger the lens the less likely is its distance from the eye to favor its harmonizing with the prescription. The plastic frame lends itself particularly to poor fitting, so that, the original selection of the frame having been slovenly, the finished product frequently slides too far down the nose and often the frame rests inelegantly, and to the patient's discomfort, on the cheek. The bows, at first snug, often become so loose that the patient is discouraged from wearing his correction or wears it with inaccurate results.

Perhaps the optical trade would be well advised to hold a national conference for the purpose of considering steps necessary in the public interest rather than solely in that of the manufacturer. Perhaps, too, some of the money spent in pretentious advertising of styles in frames and lenses could be advantageously employed in giving the public information concerning the principles involved in the fitting of spectacle lenses.

W. H. Crisp.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |

GENERAL METHODS OF DIAGNOSIS

Carlevaro, G. *The foveoscope*. *Rassegna. Ital. d'Ottal.*, 1943, v. 12, May-June, p. 187.

Carlevaro has constructed an instrument which he names the foveoscope and describes it in detail. It is used to determine the degree of central vision, both monocular and binocular, when one varies the optical adaptation of the eye by means of test lenses. Theoretical considerations are offered as to the use of the instrument to determine the light sense, visual acuity and degree of binocular vision. Eugene M. Blake.

Katz, I. H. *A focusing flashlight*. *Amer. Jour. Opth.*, 1947, v. 30, July, p. 911. (3 figures.)

Krimsky, E. *A new prism holder*. *Trans. Amer. Acad. Opth.*, 1947, March-April, p. 297.

The single prism holder designed for standard square prisms consists of an

adjustable housing connected with a vertical rod which the patient holds against the cheek. In the multiple prism holder, several square prisms with their bases in different positions may be inserted. (1 figure.) Chas. A. Bahn.

Marquez, E. Garcia. *Refracto-retinometry with the direct image*. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, Feb., pp. 126-133.

The devices for measuring fundus lesions are reviewed, and his own instrument is described. It consists essentially of a modified slit-lamp ophthalmoscope, with an incorporated round reticule, which is projected upon the retina. The reticule has concentric circles, calibrated so that it can measure lesions 1/16 mm. in size. The instrument can also be used as a refractometer by calculating the axial refractive error from the degree of displacement between the focusing lens and the condenser system. (4 illustrations, 1 table.)

Ray K. Daily.

Schepens, C. L. A new ophthalmoscope demonstration. *Trans. Amer. Acad. Ophth.*, 1947, March-April, pp. 298-301.

In this binocular instrument which was designed especially for studying detached retinas, but which is useful for all ophthalmoscopy, the indirect method is used. The illuminating unit is mounted on a stand and the observing unit is fixed by a vertical head band. The former consists of a 12-volt globe mounted in an adjustable housing to which an angled mirror and observation window are attached. The latter consists of a prism binocular magnifier with a slide for supplementary lenses and an 18-D. lens which is held in the left hand of the observer. (4 figures.)

Chas. A. Bahn.

Thorpe, H. E. A Method for visualizing the anterior segment of the globe by stereoscopic roentgenography. *Trans. Amer. Acad. Ophth.*, 1947, March-April, pp. 296-297.

A Comberg glass localizing shell is used and the outline of the eyeball is marked on the X-ray plate. (1 figure.)

Chas. A. Bahn.

2

THERAPEUTICS AND OPERATIONS

Bakker, A. The action of sulphanilamide on rabbits' lenses in vitro. *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 216-219.

Reports of experiments show that sulphanilamide, not above the therapeutic level, is quite harmless for implanted lenses of rabbits. When the concentration is elevated, it is noted that the lenses from very young rabbits became opaque; however the toxicity of sulphanilamide for lenses from adult rabbits is less pronounced.

O. H. Ellis.

Basterro. A new suture material. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, Feb., pp. 173-174.

Cortes advocates the use of nylon sutures in surgery of the lids and lacrimal sac. They are not hygroscopic and are well tolerated by the tissues, to which they do not adhere. They are slightly more rigid than silk or cotton, and have to be tied with care, lest they cut the tissues within the knot.

Ray K. Daily.

Berens, C. An illuminated retractor speculum. *Trans. Amer. Acad. Ophth.*, 1947, March-April, p. 302.

This instrument consists of an electric bulb mounted in a handle as in an ordinary hand ophthalmoscope. A regular or Arruga tip may be attached. It is designed especially for retinal and muscle surgery. (1 figure.)

Chas. A. Bahn.

Berens, C. The Luckiesh-Berens tangent screen illuminator. *Trans. Amer. Acad. Ophth.*, 1947, March-April, pp. 304-305.

This device is essentially a large frame mounted on a stand. It supports the chin rest and illuminating unit for the tangent screen. The fluorescent illumination with a color-temperature of 4,500 degrees may be varied from 1 to 100 footcandles. (1 figure.)

Chas. A. Bahn.

Berens, C. Two accommodating rules of opaque plastic. *Trans. Amer. Acad. Ophth.*, 1947, March-April, p. 303.

The longer rule is 50 cm. long, contains a slide marker, and is calibrated in inches, centimeters, and diopters. The shorter rule has a string on one end for measuring the near point of convergence. (1 figure.)

Chas. A. Bahn.

Bitran Berechit, David. **Local penicillin in ophthalmology.** *Arch. Chilenos de Oft.*, 1946, v. 2, May-June, pp. 157-177.

The drug was used locally in a total of 153 cases. The author concludes that the drug should be used locally in ophthalmology and not systemically. It may be used in collyria, ointments, and subconjunctival, retrobulbar, intra-corneal, palpebral, sacular, anterior chamber, and intravitreal injections. It should be used in combination with novocaine in high concentrations, and may be employed as a preventive of infection in cases of wounds and operations, when the infecting organism is sensitive to penicillin. (References.)

W. H. Crisp.

Cutler, N. L. **A new type of basket implant for use after enucleation.** *Surg., Gynec. and Obst.*, 1947, v. 84, April 15, pp. 792-798.

A basket (11 by 15 mm.) made of lucite (methyl methacrylate) with fenestrated sides to permit the invasion of tissue and a lucite button (5 by 8 mm.) with four holes to tie the three double-arm sutures are described. After surgery a plastic retainer is used to reduce edema and conjunctival prolapse and to help keep the basket centered. Two baskets placed in the sclera after evisceration caused extreme edema with no advantage in motion. A patient studied eight and a half months after operation showed that all the muscles became attached near the rim of the basket. Sutures are placed so that Tenon's capsule and the conjunctiva are well closed. The final prosthesis is fitted after two or three weeks. In 100 patients there was much more extensive motility than after other procedures. (13 illustrations.) H. C. Weinberg.

Duguid, J. P., Ginsberg, M., Fraser, I. C., Macaskill, J., Michaelson, I. C., and Robson, J. M. **Experimental observations on the intra-vitreous use of penicillin and other drugs.** *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 193-210.

The authors present experimental results on the intravitreal injection of penicillin and other drugs. Commercial penicillin, sodium sulphacetamide, marfanil and V. 335 (p-methyl sulphonyl benzylamine) introduced into the vitreous were highly damaging to the retina, to a degree which excluded their use clinically. Sodium sulphacetamide and pure penicillin either together or separately in the vitreous were found to diffuse rapidly into all parts of the eye, and the vitreous acted as a depot replenishing the drug lost from the other tissues. It was found that pure sodium penicillin was highly effective in the control of infections of the vitreous body, and that chemotherapeutic levels could be maintained by intravitreal injections of 2,000 units every two days. Pure sodium penicillin caused minimal retinal destruction, and its use seems indicated and justifiable in certain cases of infection.

O. H. Ellis.

Dyar, E. W. **A corneoscleral suture.** *Amer. Jour. Ophth.*, 1947, v. 30, July, pp. 909-910.

Gandolfi, C. **Vitamins C and K in ocular hemorrhage.** *Rassegna Ital. d'Ottal.*, July 1943-Dec. 1945, v. 12-14, pp. 504-515.

Gandolfi has found vitamins C and K helpful in many forms of ocular bleeding. He believes that vitamin C is indicated when there is vascular fragility which is due to a relaxation of the endothelium. In vitro it aids in coagulation, probably by activating thrombin and

inhibiting antithrombin. Vitamin K augments the action of prothrombin and thus increases the coagulability of the blood. The need of determining by laboratory tests which vitamins are lacking in each patient is emphasized. Three illustrative cases are reported.
Eugene M. Blake.

Grossmann, E. E. **Stability of penicillin in ophthalmic solutions.** Arch. of Ophth., 1947, v. 37, Feb., pp. 167-174.

The stability of penicillin was studied when dissolved in isotonic salt solution, distilled water, white ointment, Aquaphor, cod liver oil, olive oil, blood plasma, and blood serum. It was found that the ointments remained potent as long as the solutions but that the loss was rapid and wasteful. Cod liver oil and especially olive oil suspensions proved more effective than either the ointments or the saline solutions. Solutions of penicillin in blood plasma gave the best results. The solution in serum, while not so effective as the plasma solution, nevertheless, proved better than any of the ointments, oils or solutions. In general, clinical results have been good with all the penicillin mixtures when used in the treatment of properly selected patients and when applied frequently.
John C. Long.

Haas, L. R. **Intraocular penicillin in severe intraocular infections.** Jour. Amer. Med. Assoc., 1947, v. 134, June 7, p. 527.

The author reports a case of corneal perforation with hypopyon and plastic exudate, that responded to the injection of penicillin (500 units per cc.) into the anterior chamber as well as intramuscularly, and atropine locally. Vision of the affected eye was restored to 20/25.
Irwin E. Gaynon.

Hruby, K. **Ophthalmologic experiences with penicillin.** Wien. Klin. Wchnschr., 1947, v. 59, April 18, pp. 240-244.

The author reports his first experiences with penicillin which has been used in the Second Eye Clinic of Vienna since 1946. By instillation of penicillin drops of 250 units per cc. every 10 minutes for three hours, 32 out of 37 patients with ophthalmia neonatorum were cured. The continuance of this treatment for a total of 12 hours is recommended. In inflammations of longer standing a concentration of 500 units per cc. is advisable and when the cornea is involved subconjunctival injections of penicillin and, in addition, some of the older methods of treatment are indicated. Penicillin was also valuable in postoperative pyogenic infections, especially in infections after cataract extractions. No eye was lost after the treatment with penicillin was introduced, which is in sharp contrast to the experiences before its introduction. Hruby recommends early subconjunctival injections of penicillin (20,000 units per cc.) combined with puncture of the anterior chamber, intramuscular milk injections, short wave treatment, and sulfanilamide medication. Penicillin was also used as a prophylaxis before surgery by instilling a 500-unit solution for several days. When complications arose during the actual operation, a subconjunctival injection of 20,000 unit penicillin solution was done at the end of the surgical procedure. This improved the surgical results considerably. Penicillin was also beneficial in perforating injuries, blepharitis, corneal ulcers and in a case of a metastatic ophthalmia. (Literature.)

Max Hirschfelder.

Knapp, F. N. **Treatment of ocular tuberculosis.** *Wisconsin M. J.*, 1947, v. 46, June, pp. 599-603.

The primary treatment of ocular tuberculosis consists of sanatorium regimen or else rest in bed, and high-vitamine and high-caloric diet. In using radium, beta rays may be used for the anterior segment and gamma rays for the more deep seated lesions, weekly for three or four weeks in quantities that vary from 10 to 40 percent of an erythema dose. Gold sodium thiosulfate is administered twice weekly. One starts with 10 mg. and increases to 50 mg. in 5-mg. steps for 50 to 60 injections. Typhoid H antigen and typhoid vaccine may also be used. The Mantoux test and the use of old tuberculin for therapy is discussed. The importance of very small doses is emphasized.

Irwin E. Gaynon.

Krimsky, E. **Compensating convergence and accommodation device.** *Trans. Amer. Acad. Ophth.*, 1947, March-April, pp. 307-308.

This instrument consists essentially of a movable test card for each eye and a movable electric target. These are attached to a horizontal beam which somewhat resembles a stereoscope and are mounted on a vertical base. (3 figures.)

Chas. A. Bahn.

Krimsky, E. **Multiple target holder for visual field study.** *Trans. Amer. Acad. Ophth.*, 1947, March-April, p. 306.

Eight possible target combinations are mounted on a black, long wooden holder. (1 figure.)

Chas. A. Bahn.

Modell, Walter. **Pharmacologic action of some ophthalmic drugs.** *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 160-166.

The influence of surface tension, osmotic tension and pH on the absorp-

tion of drugs from solution by the conjunctiva is discussed. Recent evidence indicates that sulfonamide drugs are very effective when given systemically but that their local use is unsatisfactory. Penicillin is effective when used either locally, intramuscularly or orally. The oral administration is only about one-fifth as efficient as the intramuscular. There is a discussion of the choline drugs, mecholyl chloride, carbaminoylcholine chloride, and dibutoline.

John C. Long.

Ortin, Leoz. **Ocular postoperative endogenous infection.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, Jan., pp. 33-47.

The author recommends the utmost care with patients who are to undergo ocular surgery, especially cataract extraction. If infection is suspected, the patients must be treated before, during, and after the operation. He emphasized the use of penicillin in large doses.

J. Wesley McKinney.

Pinticart de W., Elcira. **Tuberculin therapy in Chile.** *Bol. del Hosp. Oft. de Ntra. Sra. de la Luz*, 1946, July-Oct., pp. 207-215. Reproduced from *Rev. Brasileira de Oft.*, 1946, June, p. 303 (see *Amer. Jour. Ophth.*, 1946, v. 29, p. 1330).

Rodriguez Barrios R., Fuster, B., and Gherardi, J. **Sulfamides and penicillin iontophoresis in ophthalmology.** *Clinical and experimental study.* *Arch. Urug. de med., cir., y. especialid.*, 1946, v. 29, Oct., pp. 345-360.

The concentration of sulfamides and penicillin in the anterior chamber are much greater when administered by iontophoresis than by other methods. A mixture of penicillin and sulfamides is advocated when the etiologic factor is

unknown. This method fails in drug-resisting diseases and pathology caused by toxic or allergic ocular lesions.

Irwin E. Gaynor.

Thorpe, H. E. New forceps for the removal of nonmagnetic foreign bodies from the vitreous. *Trans. Amer. Acad. Ophth.*, 1947, March-April, p. 295.

One model which is designed for scleral incisions of four or more millimeters consists of a right angled cup-like jaw regulated by thumb pressure through a 10-cm. tube. The other model is for use with smaller incisions such as a two-millimeter trephine opening. Lateral grasping cups and a notched thumb release are employed. (4 figures.)

Chas. A. Bahn.

Wiener, Meyer. *Applied anatomy in eye surgery*. *Surg., Gynec. and Obst.*, 1947, v. 84, April 15, pp. 777-786.

Important surgical anatomical facts are stressed. The thin lid skin and atrophy of its elastic fibers in old age, the looseness of the conjunctiva and the greater space on the temporal side of the globe than the nasal are discussed. The best methods for producing local anesthesia are reviewed. The bluish appearance is a guide in splitting the cornea. The thinnest portion of the cornea is at its center while the sclera is thinnest just posterior to the muscle insertions. The emissary vessels and nerves are often injured during surgery. In clean enucleations the muscle tendons need not be sewn since they fall together naturally. In orbital cellulitis an enucleation may lead to meningitis, since Tenon's capsule is continuous with the dura. The muscles vary in size, width and site of insertion. The anterior hyaloid stretches and comes forward to simulate vitreous. When cutting the iris it is well to re-

member that the vessels run parallel with the radiations. In a discussion of surgery in congenital glaucoma removal of the fetal meshwork from the angle is recommended.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Braun-Vallon, S., and Hartman, E. *Aniseiconia*. *Ann. d'Ocul.*, 1947, v. 180, Feb., pp. 65-75.

Inequalities in the size and shape of the two retinal images may be associated with the usual ametropic and heterophoric symptoms especially in psychoneurotic patients. The symptoms result from the fatigue involved in the more or less continuous effort to maintain binocular single vision. Usually the dominant eye, being less ametropic, has the smaller retinal image. Artificial aniseiconia may be produced by optically incorrect lenses especially if strong and decentered. Although few persons have retinal images which are exactly similar in size and shape, those in whom differences are less than one percent are usually free from symptoms and those who have differences of more than 1.75 percent usually have symptoms.

The ophthalmo-eikonometer and the space eikonometer are described. A French instrument somewhat similar to the latter, the logoscope, has been constructed by Grammont. The optical treatment of aniseiconia is designed to magnify the size of the smaller retinal image by the use of a thickened lens with or without changes of the curvatures used in the correction of the ametropia. Superimposed eisoconic lenses are heavy and usually impractical.

In a study of several groups treated

with cisoconic glasses the percentage of patients reported cured or greatly improved ranged from 20 to 50; of less improved from 12 to 60 and of unimproved from 25 to 30. Separating the psychoneurotic from the structural factors in the study of the cisoconic patient is not simple. (26 references.)

Chas. A. Bahn.

Briggs, A. H. Contact lenses in excelsis. *Brit. Jour. Ophth.*, 1947, v. 31, May, pp. 304-306.

This article is the account of a young pilot of the R.A.F. who had been refused pilot training because of compound myopic astigmatism of nine and six diopters. After he was fitted with contact lenses he reapplied and was accepted. The contact lenses had not been discovered. He received pilot training in England, Canada, and America, and passed numerous comprehensive medical examinations with his lenses undetected. During one of numerous missions over Germany, he was shot down. He escaped to England after many weeks wearing his lenses all the while. More rigid medical examinations and more flying followed. At the end of the war he was a test pilot and his contact lenses were still a secret. He usually wore the lenses routinely 17 to 18 hours daily and on two occasions as long as 30 to 36 hours without removing them.

The author makes a plea for more widespread use of contact lenses and also for more rigid ocular inspection during examinations which are believed to be of great importance.

Morris Kaplan.

Campbell, Dorothy. Binocular vision. *Brit. Jour. Ophth.*, 1947, v. 31, June, pp. 321-335.

The author presents a consideration of the physiological factors for the

maintenance of binocular vision. Important are the overlap in visual fields, strongly developed sense of fusion and dominance of macular over peripheral vision. In comparative studies it was found that convergence is present only in animals that possess maculas, and that body position is judged by the enervation given to ocular muscles. The localization of an image is not a purely sensory process, but a sensory-motor response, and fusion also requires a sensory-motor balance. In certain pathological conditions there is a surprising maintenance of binocular vision. It is recommended that training be started early. The use of atropine in the good eye in infancy to develop fixation in the squinting eye is advised.

O. H. Ellis.

Crisp, W. H. The study of refraction according to the technique employed by some North-American ophthalmologists. *Bol. del Hosp. Oft. de Ntra. Sra. de la Luz*, 1946, Nov.-Dec., and 1947, Jan.-Feb., pp. 217-236.

The author traces briefly the history of the technique of diagnosis of astigmatic amount and axis. He insists on the importance of preliminary diagnosis of hyperopia by adequate use of the fogging method (known in Spanish as "miopia artificial"). He also describes and illustrates his personal arrangement for mounting test charts, including a rotating cross, with a system of pulleys so that they may be moved easily from the examiner's position by the patient. It should be noted that figure 13, relating to this arrangement, has been rotated ninety degrees from its proper position. (14 figures.)

W. H. Crisp.

Fabre, P. Subjective method of measuring ametropia, without test-type or

lenses, by means of the variable bayonet. *Arch. d'Opht.*, 1946, v. 6, no. 4, pp. 436-447.

The author bases his method of measuring refraction on the original observations of Christophe Scheiner in 1619. His description of the method, which is technically complex, does not lend itself to abstraction. The author claims the method to be rapid and precise in patients having good visual acuity and normal mentality.

Phillips Thygeson.

Gaus, J. **Eccentric binocular depth perception.** *Ophthalmologica*, 1946, v. 112, Oct.-Nov., pp. 267-287.

The object of this study was to determine the acuity of binocular depth perception of eccentric retinal areas, a subject which, in contradistinction to the central acuity of stereoscopic vision, had received very little attention. The author used the method of Monjé (*Zeitschr. f. Sinnesphys.*, v. 69, p. 73 and 261) which is based upon the characteristic ability of man to recognize and to interpret in terms of depth a state of horizontal disparity of the retinal images and the characteristic inability to interpret in terms of depth a state of vertical disparity of the retinal images. A normally coordinated pair of human eyes is capable of recognizing very slight depth differences between two or three vertical rods but fails to recognize by binocular clues even very gross depth differences if the rods are placed horizontally (assuming that the observer's eyes are in primary position). Monjé's method utilizes this principle. A set of three black threads in which the center thread has been placed a certain distance forward or backward with reference to the other two threads, is first shown to the examinee in the horizontal position, that

is with the threads running parallel to the interpupillary line. In this position the existing disparity remains unnoticed if monocular clues (specifically head movements) are not permitted to come into play. Now the set of threads is rotated (toward the vertical position) until the examinee begins to perceive the greater or lesser depth of the center thread. The angle of rotation at which this sensation occurs is a measure of (inversely proportional to) the acuity of binocular depth perception. The method has been used extensively for determinations of the central (foveal) acuity of binocular depth perception. The author of the paper under review has modified the method by adding a fixation target 5 or 7 degrees away from the center of the center thread. Under these experimental conditions, keen observers are able to make consistent statements as to the position (degree of rotation) of the threads at which they first became aware of a depth difference between the three threads. The author found that eccentric retinal areas are definitely endowed with the power to recognize and interpret horizontal disparity. The upper paracentral portions of the retina proved to possess greater acuity of binocular depth perception than the lower retinal portions. The curves connecting retinal points endowed with equal acuity of binocular depth perception are very similar in shape to the isopters and to the curves connecting retinal points with equal visual acuity. Prolonged observation of the target causes a temporary drop in acuity.

P. C. Kronfeld.

Iribas, Gregorio. **Oblique astigmatism of perpendicular axes.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, June, pp. 558-561.

The author has found that ten per cent of the patients with astigmatism have oblique astigmatism of which the position of the axis in one eye is perpendicular to that of the other. This kind of astigmatism is always less than one diopter, is well corrected in nine-tenths of the patients, and is symmetrical in respect to the vertical axis.

J. Wesley McKinney.

Koch, Walter. **An improved dark adaptometer.** *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 235-237.

A redesigned and improved dark-adaptometer is presented. Filters of different colors as well as neutral filters for altering the intensity of light can be brought into position. The instrument allows for a wide range of readings on patients with gross disturbances of dark adaptation.

O. H. Ellis.

Maggiore, L. **Skiascopic refractometer for the objective examination of the total refraction of the eye in its various meridians.** *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 72, June, pp. 376-381.

Maggiore presents a picture, a diagram, a description, and directions for use, of an instrument designed to facilitate retinoscopy. It consists essentially of an adjustable mounting that embodies a retinoscope, a light source, and a battery of lenses. There are also chin- and browrests. The working distance is allowed for in the calibration of the scale and the refractive error in the various meridians may be read directly.

Harry K. Messenger.

Matteucci, P. **The foveal adaptometer.** *Rassegna. Ital. d'Ottal.*, 1943, v. 12, nos. 1-2, Jan.-Feb., p. 81.

Matteucci describes in detail a method of application of the adaptometer of Birch-Hirschfeld for the measure-

ment of the adaptation of the foveal and parafoveal regions of the retina. The retinal surfaces excited by a single luminous source in central fixation were 0.26 mm. in diameter at an angle of 1 degree, and 0.49 mm. at an angle of 2 degrees. This corresponds to a zone provided only with cones and another where these are mixed with rods. The author demonstrated that only by strict fixation limited to the fovea and with good control of fixation is it possible to study the adaptation of the rod-free area.

Eugene M. Blake.

Miles, P. W. **Factors in the diagnosis of aniseikonia and paired Maddox-rod tests.** *Amer. Jour. Ophth.*, 1947, v. 30, July, pp. 885-897. (2 figures, 1 table, 13 references.)

Neubert, Frank R. **Color vision in the consulting room.** *Brit. Jour. Ophth.*, 1947, v. 31, May, pp. 275-288.

Of 43,395 subjects who were examined for color vision 40,380 were males and 3,015 were females. Of this latter group only two were found to have defective color vision. This report deals with the males only. The 40,380 men were asked to read the original Ishihara Color Plates. Those who made a mistake (there were 2,235) were investigated by other means. They were next tested on the aviation model color lantern. Of 431 found unsafe with the plates, only 296 were found unsafe with the lantern. This proved that the plates were much more sensitive than the lantern. With the American Optical Company pseudo-isochromatic plates an even greater discrepancy resulted and a British reprint of the Ishihara plates proved entirely unsatisfactory.

A series of experimental lanterns was evolved in order to determine the influence of the size of the aperture, the

number of apertures, intensity of light and arrangement of colors. A triple apertured lantern using 10-mm. apertures with controlled illumination is the most sensitive and reliable apparatus for demonstrating defects of the color sense. Morris Kaplan.

Pérez Toril, F. Study of the causes of myopia. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, June, pp. 562-575.

A detailed study was made of 1,800 school children between 6 and 13 years of age in order to investigate the cause of myopia. The author concludes that the one and only cause of myopia is heredity. It can manifest itself or remain latent as it is governed by the laws of heredity. Prolonged close work with bad illumination can only accelerate the progress of the myopia until it reaches the point that it would have reached without any of these causes. J. Wesley McKinney.

Pignatosa, G. The accommodative power in subjects that have had iridocyclitis. *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 72, June, pp. 321-335.

From a study of eleven subjects (carefully selected so as to exclude all factors that might prejudice the results) Pignatosa concludes that iridocyclitis leads to a diminution of accommodative power. In seven cases of healed unilateral iridocyclitis there was a diminution of 0.50 to 2.00 diopters with respect to the sound eye, and in four cases of healed bilateral iridocyclitis a diminution of 0.25 to 3.00 diopters with respect to the mean values given in Duane's graph. It was observed that the accommodation fatigues more quickly in eyes that have suffered from iridocyclitis. Lens, ciliary muscle, and zonule are all factors in accommodation, but it was not determined which

of these is mainly responsible for the diminution. Harry K. Messenger.

Sloan, Louise L. Rate of dark adaptation and regional threshold gradient of the dark-adapted eye: physiologic and clinical studies. *Amer. Jour. Ophth.*, 1947, v. 30, June, pp. 705-720. (2 tables, 20 figures, 22 references.)

OCULAR MOVEMENTS

Agnello, F. Clinical symptomatology and diagnostic criterions of paralyzes of some cranial nerves consecutive to fracture of the base. *Riv. Oto-Neuro-Oft.*, 1946, v. 21, May-Aug., pp. 183-198.

Four cases of oculomotor paralyzes due to fracture of the base of the skull are reported. The clinical symptomatology and the diagnostic signs for the localization of the seat of fracture are described. The paralysis may manifest itself soon after the trauma: this happens in lesions of the base with interruption of the continuity of the nerve at the seat of the fracture or compression of the nerve by hemorrhage. In other cases the paralysis appears some time after the trauma, probably as a result of neuritis. The origin of this neuritis is discussed. (4 figures, bibliography.)

Melchiorre Lombardo.

Arruga, H. Simple tenotomy. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, Jan., pp. 17-22.

The author gives a simple operative technique for correcting squint that consists of tenotomy with retention of the tendon by means of a thread, which is easy to place and to remove. He performs a recession that never exceeds 7 mm. on the internal rectus or 12 mm. on the external rectus. (10 illustrations.) J. Wesley McKinney.

Cattaneo, Donato. An unusual case of a foreign body in the orbit. *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 72, May, pp. 257-260. (See Section 13, Eyeball and orbit.)

Cristini, Guisepe. Isolated trochlear nerve paralysis following indirect cranial trauma. *Riv. Oto-Neuro-Oft.*, 1943, v. 20, July-Aug., pp. 240-247.

A 63-year-old woman, hit by a bicycle at high speed, suffered a retrograde amnesia when she regained consciousness after 48 hours and showed an isolated unilateral paralysis of the right fourth nerve. The vulnerability of this nerve in cranial trauma is explained by its long course through the cranial cavity. In this patient there was a fracture of the skull through the inner portion of the sphenoidal fissure where the fourth nerve is adjacent to the cranial wall. (Bibliography.) K. W. Ascher.

Gibson, G. G. Marginal myotomy. *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 175-181.

The author describes his technique for marginal myotomy. This operation differs from a partial tenotomy in that it is performed posterior to the tendon, in the muscle, and consequently produces a much greater effect. Two incisions are placed in the margins of the muscle directly opposite each other, leaving a central band of intact muscle 2 to 3 mm. wide. The results of 22 cases in which this procedure was used on the external rectus are analyzed. The most suitable cases are those in which the strabismus is of short duration and the amount not too great and those in which the strabismus is of the early alternating and symmetric type.

Healy, Electra. Divergence excess:

an anomaly of the extrapyramidal system. *Amer. Jour. Ophth.*, 1947, v. 30, June, pp. 753-754.

Irvine, G. A Survey of esophoria and ciliary spasm. *Brit. Jour. Ophth.*, 1947, v. 31, May, pp. 289-304.

Ciliary spasm and pseudomyopia are intimately associated with emotional turbulence and the post-war period has produced an increasing number of patients with this manifestation. The author briefly reviews the clinical records of several patients with various types of esophoria who were benefited considerably or cured completely by orthoptic exercises. The esophoria was associated with normal divergence, with divergence weakness, and with old accommodative squint.

Ciliary spasm was found to be monocular or binocular and occurred with exophoria or esophoria, without muscle imbalance and with pseudoesophoria. Most frequent symptoms of spasm were blurred distance vision, rapid lowering of visual acuity, pain in the eyeballs, frontal headaches, and tensing of ocular muscles. These manifestations often are symptoms of true myopia but in spasm the measurements seem to vary from day to day. Treatment consisted of attempts to relieve or cure the precipitating emotional disturbance, the application of atropine twice daily and frequent orthoptic exercises. Results of therapy were generally good although relapses were not uncommon.

Morris Kaplan.

Jedlowski, Paolo. Chronic progressive ophthalmoplegia externa nuclearis. *Riv. Oto-Neuro-Oft.*, 1943, v. 20, July-Aug., pp. 203-239.

A formerly healthy woman developed unilateral blepharoptosis at the age of 19 years. Five years later other

external-ocular muscles became involved and when the patient was 25 years old, she had a complete nonfamilial, chronic, progressive external nuclear ophthalmoplegia. She never had any other neurologic or psychic disease and died of pneumonia at the age of 25 years. Examination of her central nervous system (thirty photomicrographs) revealed severe cellular changes in the nuclei of the third, fourth, and sixth nerves; no changes were found in the nuclei of Edinger-Westphal and of Perlia. This case and that published by Langdon and Cadwalader in 1928 are the only ones in the literature with both clinical and histopathologic study. (Extensive bibliography.) K. W. Ascher.

Roth, Edith. Which squints respond best to orthoptic treatment. *Amer. Jour. Ophth.*, 1947, v. 30, June, pp. 748-751. (Discussion.)

Sandifer, P. H. Chronic progressive ophthalmoplegia of myopathic origin. *J. Neurol., Neurosurg. and Psychiat.*, 1946, v. 9, July, pp. 81-83.

Chronic progressive ophthalmoplegia signifies a syndrome characterized by a slowly progressive weakness of the external ocular muscles. The term has been applied to cases of slowly increasing oculomotor palsy presumably due to degeneration of the cells of the third, fourth, and sixth cranial nerve nuclei. While the few published accounts of cases show that degeneration of the oculomotor nuclei has occurred, it has been impossible to determine whether the degeneration has been primary or secondary to some other disease process.

The case of a man, 29 years of age, is presented. He was admitted to the hospital because of a pulse rate of 30 per minute after a slight air-raid injury.

He had drooped eyelids and had had trouble in moving his eyes for many years. Although told that the drooping had existed since he was 14 years of age, he, himself, had not noticed it until he was 20. The eyes were becoming increasingly more immobile.

There was gross bilateral ptosis with compensatory contraction of the frontalis muscles. The eyeballs were almost completely fixed. There was no internal ophthalmoplegia. The movements were not improved by prostigmine. Myotonia was absent, hair distribution and testes were normal, and the Wassermann reaction was negative.

Portions of the external recti were removed for histologic study and surgery for ptosis was performed. Studies of the tissue showed that the ophthalmoplegia was of myopathic origin. This method is considered of value as an aid in the diagnosis and classification of this type of disease.

Francis M. Crage.

Swan, K. C. A squint syndrome. *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 149-154.

The author describes seven cases of a squint syndrome in which the squinting eye is so deviated that its physiologic blind spot plays a special role as a central scotoma. The history is that of a mild degree of convergent strabismus with periodic diplopia. The syndrome consists of hypermetropia or anisometropia, esotropia of 12 to 17 degrees for distance fixation, normal retinal correspondence and a binocular visual field in which the physiologic blind spot of the squinting eye constantly overlies the point of fixation. Fusional ability, with a limited amplitude of convergence and divergence, can be demonstrated by haploscopic devices adjusted to the deviation of the eyes.

The prognosis for restoration of comfortable single binocular vision is excellent if this "blindspot syndrome" is recognized and treatment is properly directed. In addition to glasses and surgical measures, orthoptic training must be utilized to develop an adequate amplitude of fusional movements and to establish a proper convergence-accommodation mechanism.

John C. Long.

Wheeler, Maynard. The management of strabismus in children. *Surg., Gynec. and Obst.*, 1947, v. 84, April 15, pp. 787-791.

The author stresses the importance of obtaining an early accurate vision. If the squint is firmly monocular, the squinting eye is amblyopic. If there is alternation even in only one field, one can assume approximately equal vision. The Hirschberg corneal reflex test, White's cover test, and the prism reflex tests are discussed. Treatment should be given as early as possible with glasses or surgery to avoid secondary muscle changes and to obtain binocular vision. Accommodative squints do not often appear before two years of age. Orthoptic exercise is desirable. Only if there is a hyperopia of four diopters or more and the squint is eliminated with glasses should operation be postponed indefinitely. Some general principles in muscle surgery are offered.

Patz-Arnall. An eruptive fever involving the skin and mucous membranes (Stevens-Johnson disease). *New England J. Med.*, 1947, v. 236, May 8, pp. 697-700.

An eight-year-old boy had an upper respiratory infection with fever, tearing, photophobia and sore throat. The next day blisters developed on the upper lip, forearm and abdomen and on the third day an acute keratoconjunctivitis followed. A balanitis developed subsequently. A pseudodiphtheritic membrane covered the cornea and sclera. During the second week the membrane sloughed away and left ulcers that healed with opacification and symblepharon. The final visual acuity was 20/60 in each eye.

Irwin E. Gaynon.

Romero, Eduardo. Operative procedure in the treatment of posterior symblepharon. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Nov., pp. 1161-1162.

An easy technique for the treatment of posterior symblepharon is given. One goes through the adhesion from side to side with a needle carrying several threads. Later, when the tunnel is well epithelialized, the bridge is cut as in an

anterior symblepharon. Three cases are reported. J. Wesley McKinney.

Rostkowski, L. The operations of Hotz-Anagnastakis, of Denig, and of canthoplasty as performed in the anti-trachoma teaching organization. *Arch. d'Ophth.*, 1946, v. 6, no. 4, pp. 456-459.

The author reports observations on the efficacy of various trachoma operations. The most commonly employed operation was that of Hotz-Anagnastakis for cicatricial entropion which was used in 1,138 cases. The technique of the operation is described in detail and a modification to increase its effectiveness is reported. A canthoplasty was almost invariably performed at the same time. Of 121 patients which were followed for from one to five years after the operation, good functional results were obtained in 91, satisfactory results in 16, insufficient results in 12, and unfavorable results in 2. Good cosmetic results were obtained in 63, satisfactory cosmetic results in 49, and unfavorable cosmetic results in 9.

There were 230 operations performed for relief of advanced pannus according to the method of Denig. The author describes Denig's technique for the operation as well as his own modification. The mucous membrane grafts invariably survived. Of 85 patients observed for a year or more after operation a good cosmetic result was obtained in 78 and a poor result in 7. In five of the latter the graft appeared as a conspicuous red tumor. The effect on the pannus was considered favorable in 56 patients, in 18 the results were questionable, and in 11 unsatisfactory. Sixty-nine of the patients stated that they believed that the operation had improved their vision whereas 13 claimed no improvement. In a second series of 28 patients followed for a

year or more but in which the follow-ups were not made by the author personally, there were 26 with good cosmetic results and two with unsatisfactory cosmetic results. Twenty of the 26 claimed improvement in vision.

The author concludes that the operations described have proved satisfactory. Phillips Thygeson.

Selfa, Enrique. Irradiation of the thymus in the treatment of vernal catarrh. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, Feb., pp. 175-177.

Two patients with vernal catarrh, resistant to the usual forms of therapy, were promptly relieved of their subjective symptoms by irradiation of the thymus. Ray K. Daily.

Stern, H. J. Conjunctivitis due to exposure to dimethyl-sulfate. *Brit. Jour. Ophth.*, 1947, v. 31, June, pp. 373-375.

A detailed case report of a worker who developed a severe bilateral conjunctivitis in the palpebral fissures due to exposure to dimethyl-sulfate is presented. The condition permanently cleared after change of occupation. It was noted that not all workers were similarly affected. The literature is discussed. O. H. Ellis.

6

CORNEA AND SCLERA

Benner, R. Is filamentary keratitis infectious? *Ann. d'Ocul.*, 1947, v. 180, March, pp. 140-141.

Infection may play a more or less important role in the causation of this condition. Two cases are described in which filamentary keratitis quickly subsided after the use of penicillin ointment. Chas. A. Bahn.

Borsello, G. Familial degeneration of

the cornea. *Rassegna Ital. d'Ottal.*, 1943, v. 12, March-April, pp. 143-163.

Four cases of corneal dystrophy in two families are reported. All were of the nodular type, bilateral and of various forms—grayish-white spots, rings, and dots, all limited to the central and paracentral zone. In two of the patients the lesions were seated in the periphery of Bowman's membrane, and in the other two in the superficial layers of the parenchyma. All of the patients had a slight increase of blood calcium.

The author believes the cause to be a nutritional disturbance producing functional modification of the trophic nerves, central or peripheral. These changes are hereditary and probably result, directly or indirectly, from a general disfunction of the organs of internal secretion. (4 figures.)

Eugene M. Blake.

Colombo, G. The pathogenesis of band-like opacity of the cornea. *Rassegna Ital. d'Ottal.*, 1943, v. 12, nos. 1-2, Jan.-Feb., p. 31.

A 51-year-old man was seen after two years of trouble with both eyes. Examination disclosed a typical band-like opacity of the cornea, associated with bilateral cornea guttata. The writer agrees with the explanation of Schick that the band-like opacity results from an alteration of the cornea-aqueous barrier arising in the endothelium of Descemet's membrane. The true corneal changes develop later from this source. The cornea guttata is probably a senile or presenile dystrophy and has been previously described in association with band-like opacity. (2 figures.)

Eugene M. Blake.

Di Fernando, R. Osseous fragility and blue sclerotics. *Rassegna Ital. d'Ottal.*, 1943, v. 12, May-June, p. 196.

The principal and secondary signs of the syndrome are presented. A patient, 29 years of age, had all the manifestations of this syndrome except the auditory changes. The study of the genealogical tree shows various members with the characteristic scleral color, some with and some without the osseous alterations. Only the father of the patient had all the signs of the complete syndrome. The modification of manifestation at different ages suggests the probable intervention of endocrine factors. (6 figures.) E. M. Blake.

Favaloro, G. Endotheliazation of the anterior chamber and secondary keratitis. *Rassegna Ital. d'Ottal.*, 1943, v. 12, Jan.-Feb., p. 3.

Favaloro describes a pathologic condition which consists of changes in the structures of the anterior segment of the globe. These he divides into three phases, the first of which is a primary alteration of Descemet's membrane and endothelium with a subacute inflammatory reaction in the iris. In the second phase there is a secondary participation of the corneal parenchyma and the epithelium. In the third place corneal opacities, more or less extensive and dense, appear principally in the anterior layers of the cornea and the epithelium.

The disease lasts for weeks or months and the lesion is mostly located in the central and paracentral region and is similar to other forms of keratitis profunda. The author proposes the name endothelio-irido-descemetitis and believes it to be a distinct entity. (5 figures.)

Eugene M. Blake.

McNicholas, P. J. Phlyctenular keratoconjunctivitis as observed in Normandy. *Ann. d'Ocul.*, 1946, v. 179, Dec., pp. 619-623.

Thirty-two cases of phlyctenular ker-

atoconjunctivitis were observed in a study of 924 tuberculin-sensitive persons made during the early part of 1946. Normandy was one of the most heavily devastated areas in France during the war and hygienic and dietetic conditions were extremely poor. In 18 of the patients with ocular disease a primary thoracic infection was observed radiographically.

Chas. A. Bahn.

Soria. *Leishmania interstitial keratitis*. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, June, pp. 544-549.

A young man had acne on his face for three years before developing an ocular complaint. *Leishmania tropica* was found in one of the lesions. In his left eye he had pericorneal injection, photophobia, epiphora, and interstitial keratitis without corneal ulcer. The right eye was normal. All laboratory tests were negative. The anti-leishmania treatment was effective in healing the skin lesions and ocular disturbances. The keratitis left a faint corneal opacity.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Corcelle, L. On meningeal reactions in sympathetic ophthalmitis. Brit. Jour. Ophth., 1947, v. 31, June, pp. 366-372.

The author discusses the literature and presents three cases of sympathetic ophthalmitis with meningeal reaction. Examination of cerebrospinal fluid showed lymphocytic meningitis which varied in intensity with the severity of the ocular disease. In severe ocular inflammations there was a more marked meningeal reaction, but the prognosis could not be correlated with

the reaction. This possible path of transmission of a filterable virus of unknown origin suggests that sympathetic ophthalmitis may be a lymphocytic uveomeningitis. O. H. Ellis.

Crespi, G. Persistent hemorrhages in the anterior chamber. Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, Jan., pp. 23-32.

Four cases of persistent hyphema with a lesion of the iris with or without surgical procedure are reported. In one, the hemorrhage was associated with a chronic, probably tuberculous, iridocyclitis. An iridectomy had been performed a year before. In a second patient postoperative hyphema increased with cyclodiathermy when this procedure produced a low ocular tension in an eye with hypertension due to an old pupillary seclusion and a degenerate iris. In a third eye with chronic syphilitic iritis hypertension was relieved by means of miotics. Slight hyphema appeared at the level of the synechia. In a fourth eye there was persistent hemorrhage after a surgical procedure with a lesion of the iris. In all cases degenerative lesions of the iris were found. (Several illustrations.)

J. Wesley McKinney.

Peris, E. Fornes. A histopathologic report of a case of choroideremia. Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, Feb., pp. 134-138.

The eyes of an infant that had died of malnutrition, were enucleated post-mortem, for the study of the lagophthalmic corneal ulcers. Microscopic examination of the eyes revealed total absence of the choroid. The microscopic appearance is described and illustrated with six photomicrographs. The etiology of this rare anomaly is discussed.

Ray K. Daily.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month.

DEATHS

Dr. Warren Beagle Davis, Philadelphia, Pennsylvania, died July 7, 1947, aged 65 years.

Dr. Charles John Edwards, Vicksburg, Mississippi, died March 13, 1947, aged 62 years.

Dr. Delbert Oscar Kearby, Indianapolis, Indiana, died April 10, 1947, aged 68 years.

Dr. Charles Alford Maghy, San Diego, California, died April 27, 1947, aged 62 years.

Dr. William Robert Thompson, Fort Worth, Texas, died May 1, 1947, aged 84 years.

Dr. Arthur Morris Zinkhan, Washington, D.C., died April 30, 1947, aged 56 years.

ANNOUNCEMENTS

20TH GRADUATE FORTNIGHT

The New York Academy of Medicine, 2 East 103 Street, New York 29, announces the 20th Graduate Fortnight from October 6 to 17, 1947. This year the Graduate Fortnight will be devoted to the study of Disorders of Metabolism and the Endocrine Glands. The program includes—morning panel discussions, afternoon clinics, evening lectures, scientific exhibits and demonstrations. The registration fee is five dollars. A program will be mailed to every Fellow of the Academy without request and to other physicians upon request. Address request to Dr. Mahlon Ashford, 2 East 103 Street, New York 29, New York.

Evening Lectures

OCTOBER 6—Opening Address—George Baehr, *President, The New York Academy of Medicine. The Ludwig Kast Lecture—The Diseases of Adaptation, With Main Emphasis Upon Hypertension—Hans Selye, Institute of Experimental Medicine and Surgery, University of Montreal*

The Carpenter Lecture—Adaptation Syndrome In Man—John S. L. Browne, McGill University Clinic of the Royal Victoria Hospital, Montreal

OCTOBER 7—Energy Metabolism In Obese Persons—Louis H. Newburgh, *University of Michigan Medical School*

Psychological Aspects of Obesity—Hilde Bruch, College of Physicians and Surgeons, Columbia University

OCTOBER 8—Relation Of The Adrenals To Immunity—Abraham White, *Yale University Clinical and Experimental Studies On Adrenal Cortical Hyperfunction—Louis J. Soffer, Mount Sinai Hospital*

OCTOBER 9—Metabolic Consequences of Im-

mobilization—John E. Deitrick, *Cornell University Medical College*

Use of Androgens In Women—Ephraim Shorr, Cornell University Medical College

OCTOBER 10—Studies In Intermediary Metabolism Conducted with the Aid of Isotopic Tracers—DeWitt Stetten, Jr., *Harvard University Medical School*

The Excretion of Urinary Steroids In Health and In Disease—Konrad Dobriner, Sloan-Kettering Institute for Cancer Research

OCTOBER 13—Disturbances In Electrolyte Metabolism In Man and Their Management—Daniel C. Darrow, *Yale University School of Medicine*

Role of Amino Acids In Nutrition—William C. Rose, University of Illinois

OCTOBER 14—Metabolic Functions In Old Age—Nathan Shock, *U. S. Public Health Service, Baltimore City Hospital*

General Aspects of Cushing's Syndrome—E. C. Reifenstein, Jr., Sloan-Kettering Institute for Cancer Research of the Memorial Hospital Cancer Center

OCTOBER 15—Hormonal and Chemical Factors Regulating Thyroid Function—Rulon W. Rawson, *Harvard University Medical School*
Some Clinical Experiments With Antithyroid Compounds—Edwin B. Astwood, Joseph H. Pratt Diagnostic Hospital, Boston

OCTOBER 16—Testicular Dysfunction, Some Clinical Aspects—E. Perry McCullagh, *Cleveland Clinic, Cleveland*

Use of Androgens In Men—Carl G. Heller, University of Oregon Medical School

OCTOBER 17—Why Do Women Abort—Arthur T. Hertig, *Harvard University Medical School*
Morphological Basis for Menstrual Bleeding—Joseph E. Markee, Duke University

WILL LOAN SHERSHEVSKAYA'S BOOK

Transplantation of the Cornea Using Freshly Conserved and Fixated Material, by O. I. Shershevskaya, assistant in the Eye Clinic of the Institute of Post-Graduate Medical Study, Novosibirsk, U.S.S.R., 1940.

This book, which was presented in the form of a thesis for a degree of Medical Sciences by one of Dr. V. P. Filatov's former pupils, has been made available to ophthalmologists in English through a generous financial contribution from The Eye-Bank for Sight Restoration.

There are three typewritten copies available of some 233 pages. It has been divided into several parts: Historical, Surgical Technique, Experimental, and Some Observations on the

Results of the Operation on Human Subjects. Of greatest value and interest to ophthalmologists who are familiar with corneal transplantation is the chapter on the historical review.

These books will be loaned upon request, free of charge, to ophthalmologists who are interested. Address: The Eye-Bank for Sight Restoration, Inc., 210 East 64th Street, New York 21, New York.

REFRESHER COURSE REGISTRATION

The Chicago Ophthalmological Society will give a 40-hour refresher course December 8 to 13, 1947. The faculty will include members of the eye departments of The University of Chicago, The University of Illinois, Loyola University, and Northwestern University, and staff members of all of the principal hospitals of Chicago. Instruction will consist of didactic and practical courses, emphasis being placed on the practical courses given to small groups. Physicians practicing in the fields of ophthalmology and eye, ear, nose, and throat are eligible for the course. The fee will be \$100.00. For details write to the registrar, Miss Maude Fairbairn, 8 West Oak Street, Chicago, Illinois.

MISCELLANEOUS

STANFORD UNIVERSITY APPOINTMENTS

Dr. Hans Barkan, now clinical professor of ophthalmology and chief of the division of ophthalmology at Stanford University School of Medicine, became emeritus on September 1, 1947.

Dr. Alfred E. Maumenee, Wilmer Ophthalmological Institute, Baltimore, has been appointed professor of surgery assigned to ophthalmology to succeed Dr. Barkan. Dr. Maumenee will not assume his duties at Stanford University until September 1, 1948. In the meantime, Dr. Dohrmann Kaspar Pischel, clinical professor of ophthalmology at Stanford, will act as chief of the division until Dr. Maumenee can join the staff.

TEMPLE UNIVERSITY OPHTHALMOLOGY CHIEF

Dr. Glen G. Gibson, Philadelphia, has been appointed professor and head of the Department of Ophthalmology at the Temple University School of Medicine and Hospital, succeeding Dr. Walter I. Lillie, who died February 21st. Dr. Gibson, a graduate of St. Louis University School of Medicine, St. Louis, in 1930, has been an associate professor of Ophthalmology at Temple University School of Medicine. He interned at Providence Hospital, Detroit, and

was a fellow in Ophthalmology at the Mayo Clinic, Rochester, Minnesota, 1931-1934.

UNIVERSITY OF ILLINOIS APPOINTEE

Dr. William F. Hughes, Jr., associate professor of Ophthalmology, Indiana University School of Medicine, Bloomington-Indianapolis, has been made head of the Department of Ophthalmology at the University of Illinois College of Medicine. Dr. Hughes was graduated in medicine from Johns Hopkins University School of Medicine, Baltimore, in 1938, interned at Johns Hopkins Hospital and later served as assistant resident and resident ophthalmologist of the outpatient department. During the war he conducted research on treatment of chemical burns of the eye at Johns Hopkins University for the Office of Scientific Research and Development.

OHIO STATE APPOINTS CULLER

Appointment of Dr. Arthur M. Culler, a member of the Department of Ophthalmology staff at Ohio State University since January, 1946, as chairman of the department has been announced by President Howard L. Bevis.

Dr. Culler succeeds the late Dr. Albert D. Frost, who headed the department in the Ohio State University College of Medicine from 1929 until his death November 15, 1945. Dr. Claude S. Perry has been acting chairman and will now continue as an associate professor.

NEW ORLEANS EYE-BANK ORGANIZED

The newly organized Eye-Bank in New Orleans, Louisiana, will have the coöperation of the Louisiana State University Medical School and the Tulane University Medical School and Hospital. It is located in the Hutchinson Memorial Building, and Mrs. Orville Ewing is serving as executive director. The officers are Charles E. Fenner, president; Dr. William B. Clark, 1st vice president; George L. Hardin, 2d vice president; John F. Reilly, treasurer; and John W. Sims, secretary.

SOCIETIES

INSTITUTE PENIDO BURNIER OFFICERS

The Medical Association of the Instituto Penido Burnier has appointed the following officers for 1947-1948: President, Dr. João Lech, Jr.; 1st secretary, Dr. Guedes de Melo Fo.; 2nd secretary, Dr. Alberto Galo; librarian-treasurer, Dr. Leôncio de Suza Queiroz; editors of the *Arquivos de Instituto Penido Burnier*, Dr. Penido Burnier, Dr. Gabriel Pôrto, and Dr. F. J. Monteiro Sales.

FRONTISPIECE (HADEN). CROSS SECTION OF OPTIC STALK SOON AFTER ENTRANCE OF
AXONS OF GANGLION CELLS OF RETINA.

THE DEVELOPMENT OF THE ECTODERMAL FRAME-
WORK OF THE OPTIC NERVE, WITH ESPECIAL
REFERENCE TO THE GLIAL LAMINA
CRIBROSA*

HENRY C. HADEN, M.D.

Houston, Texas

When the optic stalk first appears, its wall is composed of undifferentiated epithelial cells (fig. 1) differing in no way from those of the optic vesicle and brain wall with which it is in continuity.

At about the 15-mm. age, the axons of the ganglion-cells of the retina grow back into the wall of the optic stalk on their way to the brain, which they reach at the 20-mm. age. The entrance of the axons, the optic-nerve fibers, into the stalk wall initiates a great change in the epithelial cells of the stalk wall. Their nuclei become somewhat oval, and the cell protoplasm vacuolated and partially absorbed. The result is an irregular arrangement of starlike cells with anastomosing processes through which the optic-nerve fibers pass (*frontispiece*). These are the glial cells which form the sustentacular tissue, framework, or septa of the optic nerve in young embryos.

At first the glial cells are scattered irregularly throughout the nerve, and the optic-nerve fibers passing among them are not in parallel rows. Later on the glial cells show a tendency to line up in longitudinal rows between the bundles of optic-nerve fibers to form the primary

septa. In longitudinal sections of a 20-mm. embryo (fig. 2) the early condition is apparent. The optic-nerve fibers are not in bundles but course irregularly throughout the nerve, and the glial cells have no definite pattern (fig. 2).

Cross section of the fellow nerve of the 20-mm. embryo made back of the globe, near the entrance of the hyaloid artery, shows this lack of design (fig. 3) but about the middle of the orbital part of the nerve (fig. 4) the glial cells congregate about its axis in a stellate arrangement. In the posterior third of the nerve (fig. 5) the residual lumen of the optic stalk is seen with glial cells surrounding it. The cells forming its lining have the appearance of the original epithelial cells. If the lumen of the stalk is followed back (fig. 6) it will be found to pass into the recessus opticus in the telencephalon. At the 29-mm. age (fig. 7) longitudinal sections show more regularity of arrangement but the optic-nerve fibers are not in bundles and the glial cells are not lined up in parallel rows to form septa. Cross section of the fellow nerve of the 29-mm. embryo (fig. 8) in the region of the anlage of choroid shows more definite design. The cell bodies are more regularly spaced and the anastomosing processes form a network through

* Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

which the nerve fibers pass. The appearance is very much that of the definitive glial lamina cribrosa.

There is not much regularity of pattern of the nerve as a whole until the 45-mm. age is reached when some suggestion of rows of glial cells are seen (fig. 9). Also the peripheral glial mantle is well developed (fig. 9). It is recognized as a layer of cells continuous with the pigment layer of the retina. It leaves the pigment layer at almost a right angle and passes brainward, covering the outer surface of the optic nerve. As it is a continuation of the pigment layer of the retina, which is a modification of the original wall of the optic vesicle, the peripheral glial mantle must be composed of the original epithelial cells forming the outer surface of the stalk. Processes from it enter into the nerve but no mesodermal tissue other than that accompanying the hyaloid artery is found in the nerve at this age. At the end of the optic nerve adjacent to the vitreous there is a clumped mass of cells called "Bergmeister's Papilla" (fig. 9), the analogue of the pecten of birds. It is composed of original epithelial (ectodermal) cells which were isolated by the curving nerve fibers as they grew back from the inner wall of the optic cup into the stalk (fig. 9).

The nerve of the 67-mm. embryo (fig. 10) shows much more regularity of detail when seen in longitudinal section. The glial cells are lined up in parallel longitudinal rows between the bundles (fasciculi) of nerve fibers in the orbital portion. In the distal end of the nerve, that opposite the anlagen of the choroid and sclera, the arrangement is different. Here the glial cells lie in well-defined parallel rows with the long axes of their nuclei at right angles to the nerve fibers. These constitute the anlagen of the laminae cribrosae (fig. 10). Until the

67-mm. age, the optic nerve is composed of only ectodermal tissue with the exception of the mesoderm accompanying the hyaloid artery. At this age capillaries accompanied by fibroblasts grow into it from the anlage of the pial sheath. This is the first invasion of the mesoderm which is to grow along the columns of glial cells which form the primary septa of the nerve. From this age on the mesoderm grows into the nerve and follows the columns of glial cells as a grapevine climbs on an arbor. In this manner the mesoderm replaces most of the glial cells and forms the definitive fibrous connective-tissue septa of the optic nerve. However, there are always gaps in the mesodermal septa which are filled in by glial cells. By the 97-mm. age (fig. 11) there is much more mesoderm in the orbital portion of the nerve but there is none in the region opposite the choroid and sclera, the anlagen of the laminae cribrosae. Cross sections through this location show the glial cells and processes forming a network through which the nerve fibers pass. The appearance is very much as it was when the glial cells first formed.

At about $4\frac{1}{2}$ months of age (fig. 12) a change takes place in the distal end of the nerve. Rows of glial cells from Bergmeister's Papilla grow out into the vitreous on either side of the hyaloid artery forming its glial sheath. There is a space between the sheath and the walls of the artery. This sheath disappears before birth. By the 360-mm. age (circa 7 months) many fibrous connective-tissue fibers have grown into the network of glial cells opposite the anterior third of the sclera to form the connective-tissue lamina cribrosa (lamina scleralis). They are a direct ingrowth from the sclera (or the border tissue, which is the same) and not a forward growth of the septa

of the orbital portion of the optic nerve. These mesodermal fibers increase in number until, at the 500-mm. age (fig. 13), they form the major portion of the scleral lamina cribrosa. The portion of the nerve anterior, or distal, to the lamina scleralis is not invaded by mesoderm at any time but remains ectodermal throughout life. Toward the end of fetal life, the nerve fibers in the orbital portion of the optic nerve are medulated, the medulation ceasing at the posterior, or brain side, of the lamina scleralis (connective-tissue lamina cribrosa). The nerve fibers anterior to the connective-tissue lamina cribrosa are naked axis cylinders. The glial cells and fibers that lie in front (fig. 14) of the lamina scleralis and opposite to the cho-

roid form the glial lamina cribrosa, which is also called lamina chorioidalis (fig. 14).

The glial lamina cribrosa occupies a unique position for it is the framework of the optic disc (fig. 15) and the ophthalmoscopic picture varies with its arrangement. Furthermore, it participates in all pathologic processes involving the intraocular end of the optic nerve and it must be destroyed before the typical glaucomatous cup can be produced.

1914 Travis Street.

The illustrations which follow were made from unretouched photographs of sections of human embryos and fetuses in my private collection.

STREPTOMYCIN IN OPHTHALMOLOGY*

JOHN G. BELLOW, M.D., AND CHESTER J. FARMER, PH.D.
Chicago, Illinois

Thousands of different strains and species of actinomyces, fungi, and bacteria have been investigated for antibiotic production and therapeutic usefulness; however, only penicillin and streptomycin, thus far, have proved to be of real therapeutic importance. Of the two, penicillin is far more valuable, yet streptomycin is superior to penicillin in the control of certain specific organisms. The therapeutic possibilities of streptomycin in ocular infections has aroused a great deal of interest. The literature is scanty and it must be emphasized that streptomycin therapy in ocular infections is still in the experimental stage.

Leopold and Nichols¹ have demonstrated that streptomycin administered to rabbits in dosages of 10,000 mcgm. per kg. body weight appears in the conjunctiva, sclera, extraocular muscles, and aqueous humor. Much larger doses (100,000 mcgm. per kg. body weight) are necessary for streptomycin to become detectable in the cornea, vitreous, chorioretinal tissues, and optic nerve. Streptomycin did not penetrate the intact cornea, but it readily penetrated the cornea if it was abraded or if iontophoresis was employed.

Owens² reported that an *E. coli* infection of the cornea responded satisfactorily to local treatment with this antibiotic. Alberstadt and Price³ stated that streptomycin lessens the healing time of corneal infections. We⁴ showed that intraocular injections of streptomycin, if

administered in 6 to 8 hours, prevented experimentally produced vitreous infections. We found that streptomycin was unexcelled for the treatment of experimental and clinical *B. pyocyaneus* infections of the cornea. This antibiotic was also of value in some types of acute and chronic conjunctivitis. Molitor⁵ reported that streptomycin even in the most purified form possesses neurotoxic properties. The large systemic doses required for the antibiotic to reach a detectable although not necessarily therapeutic level in the cornea, vitreous, chorioretinal tissues, and optic nerve might produce, during prolonged treatment, neurotoxic disturbances in man. If it were possible to achieve adequate therapeutic concentrations by local methods of administration, the toxic manifestations accompanying systemic administration would be avoided.

PURPOSE OF THIS REPORT

The purpose of this report is to describe the following investigations:

1. Factors which influence the penetrability of streptomycin through the cornea.
2. Local tissue tolerance following surface application and intraocular injection of streptomycin.
3. The effectiveness of streptomycin therapy in vaccinia keratitis with secondary infections.
4. Factors which influence the penetrability of streptomycin through the cornea.

EXPERIMENTAL PROCEDURE

We have confirmed the work of Leopold and Nichols in that streptomycin does not penetrate the normal cornea. In a series of normal rabbits anesthetized by intravenous injection of nembutal,

*From the Departments of Ophthalmology and Biochemistry, Northwestern University Medical School, Chicago, Illinois. This research was done under a contract between Navy Program for Basic Research and Northwestern University.

streptomycin hydrochloride, in concentrations of 5,000, 10,000, and 50,000 mcgm. per ml. of physiologic salt solution, was applied as a corneal bath by means of plastic eye cups for periods of 15 minutes to 4 hours. At the end of the designated period, the cup was removed, and the cornea and cul-de-sac were thoroughly washed with a stream of normal saline from a wash bottle. The aqueous was then withdrawn through a limbal puncture by means of a sterile 27-gauge needle attached to a tuberculin syringe. The streptomycin concentration of the aqueous was then determined by the method of Heilman⁶ using *B. megatherium*. Values of less than 6.25 mcgm. streptomycin per ml. of aqueous could not be accurately determined by this method because of the small amount of aqueous (0.2 ml.) obtainable. They were, therefore, considered negative. Fluorescein staining at the end of the period established the absence of corneal damage. Out of the entire series of 24 rabbit eyes, only one showed a measurable amount. In this single animal a concentration of 50,000 mcgm. per ml. applied for three hours resulted in a concentration of 12 mcgm. per ml. aqueous.

Since the normal cornea prevents streptomycin from reaching the aqueous, attempts were made to increase the penetrability by the following means:

1. CORNEAL PENETRABILITY OF STREPTOMYCIN

a. Iontophoresis (ion-transfer). Leopold and Nichols showed that by means of iontophoresis, streptomycin could be made to penetrate the cornea in considerable amounts so that the concentrations in aqueous reached 30 to over 70 mcgm. per ml.

In preliminary electrophoretic experiments with solutions containing 100 mcgm. of streptomycin (HCl) per ml., assay of samples taken from the electrode chambers showed a concentration of less

than 50 mcgm. at the anode and over 100 mcgm. at the cathode with currents of 0.8 to 0.9 milliamperes at 44 volts. In an extirpated rabbit eye, iontophoresis with a solution of 1,000 mcgm. streptomycin (HCl) per ml., using 22 volts and 2 milliamperes for 30 minutes with the anode connected to the solution cup and cathode inserted through the optic nerve into the vitreous, gave an aqueous concentration of 100 mcgm. per ml. In the living rabbit eye, iontophoresis of a solution containing 10,000 mcgm. per ml. for 30 minutes with a current of 2 milliamperes at 22 volts produced a concentration of 25 mcgm. streptomycin per ml. aqueous. These experiments clearly indicate that a therapeutic level of streptomycin may be achieved in the aqueous by means of iontophoresis.

b. Use of wetting agents. Bellows and Gutmann⁷ employed wetting agents with sulfonamides and showed increased concentrations in the aqueous. It, therefore, seemed logical to follow these studies in an attempt to increase penetration for streptomycin to such an extent as to obtain effective therapeutic levels in the aqueous. Using the procedure already described, one drop of aerosol (O.T.) (0.5-percent solution) was added per ml. of streptomycin solution employing concentrations of 5,000, 10,000, and 50,000 mcgm. per ml. for periods of 30 minutes, 1 hour, and 2 hours. Assay of the aspirated aqueous revealed values of 25 to 50 mcgm. per ml. when a corneal bath with a concentration of 50,000 mcgm. streptomycin per ml. of solution was used for one hour. With 5,000 and 10,000 mcgm. streptomycin per ml., the values were below 6.25 units per ml. aqueous for periods of 30 and 60 minutes. In two cases, where 10,000 mcgm. were employed for a period of two hours, values of 25 mcgm. per ml. of aqueous were obtained.

In three eyes, where 10 drops of 0.5-

percent solution of aerosol (O.T.) were added to 1 ml. of solution containing 50,000 mcgm. of streptomycin (HCl), values of over 100 mcgm. streptomycin per ml. aqueous were obtained. However, this concentration of aerosol produced macroscopic corneal changes, as evidenced by staining of the cornea with fluorescein.

These studies indicate that corneal penetration to streptomycin may be safely achieved by the cautious use of relatively low concentrations of aerosol. Further work is in progress with other wetting agents.

c. The abraded or the inflamed cornea. Leopold and Nichols report values ranging between 14 and 21 mcgm. streptomycin per ml. aqueous 15 minutes after "drop installations" of a saline solution of streptomycin containing 50,000 mcgm. per ml. in rabbits with abraded corneas. In our experiments using the eye cup, solutions containing 10,000 mcgm. or more per ml. in saline for two hours gave values of over 100 mcgm. per ml. aqueous. Clinically streptomycin will be used on inflamed corneas. For this reason a study was undertaken to determine penetrability through the infected cornea. For this purpose 15 rabbit corneas were inoculated with vaccinia. When definite signs of corneal infection were manifest, the penetration studies were carried out using the eye cup with a 10,000 mcgm. streptomycin (HCl) per ml. of saline solution for 15-, 30-, and 60-minute periods. With the exception of two eyes, the values in the aqueous ranged from 25 to 200 mcgm. per ml. There was no apparent relation between the longer and shorter intervals of bathing and the assay values. This may possibly be explained on the basis of the size of the corneal lesions. Thus, it is noteworthy that in corneal infections local applications lead to therapeutic concentration of streptomycin in the aqueous humor.

2. LOCAL TISSUE TOLERANCE OF STREPTOMYCIN

a. Effect on regeneration of the corneal epithelium. As shown by Bellows,⁸ the cornea is an excellent medium to ascertain information relative to the local tissue effect of drugs. Molitor noted that instillation in the rabbit eye of buffered solutions of streptomycin available at that time, containing "500 to 1,000 units per cubic centimeter," results in an immediate inflammatory reaction which disappears in 12 to 24 hours. Our experience with the present commercial streptomycin (HCl), as well as the highly purified streptomycin-calcium-chloride complex, shows that saline solution, containing 10,000 mcgm. per ml., upon instillation into the rabbit and human eye is well tolerated as evidenced by no greater degree of conjunctival redness than that occurring upon similar treatment with accepted ophthalmic solutions.* In a series of 30 clinical cases in which this concentration was employed for instillations into the eye, only one patient complained that the eyes seemed worse after use of the antibiotic. In no case was any injury to the cornea or conjunctiva noted.

In addition to the production of conjunctival redness and staining reaction of the cornea, another means of evaluating local toxicity of a drug is its influence upon the cornea following removal of epithelium by abrasion with sterile gauze. For these studies a series of rabbit corneas were abraded with gauze, and the completeness of denudation was established by staining with fluorescein. Of these animals, six received instillations of a saline solution of streptomycin (HCl) containing 10,000 mcgm. per ml. in the right eye, reserving the left as a control receiving saline simultaneously with the

* The samples of streptomycin used by us were kindly furnished by Dr. Robertson of Merck and Company, Inc., and show negative or minimal histaminelike effects.

treated eye. Two drops were instilled five times daily between the hours of 9 a.m. and 5 p.m. until the corneal epithelium had regenerated as evidenced by absence of

Fig. 1 (Bellows and Farmer). Abraded cornea receiving 10,000 mcgm. streptomycin per ml. saline.

staining with fluorescein. A second group of six rabbits was treated similarly with a streptomycin solution containing 50,000 mcgm. per ml., while a third group of six rabbits received 20 mg. of streptomycin powder at similar intervals.

In these experiments, corneas of the rabbits receiving instillations of the solution containing 10,000 mcgm. per ml. (fig. 1) healed at the same rate as those controlled with saline solution (3 to 5 days), thus showing no retardation in corneal regeneration due to the antibiotic solution. However, in rabbits receiving instillations of the 50,000-mcgm. concentration, there was a definite delay in healing to at least twice normal. The streptomycin powder delayed the regeneration of the epithelium even more markedly than the solution containing 50,000 mcgm. per ml. Furthermore, the cornea treated with either the 50,000-mcgm. concentration or with powdered streptomycin when finally healed showed marked vascularization

and marked scar formation (fig. 2).

Since it is generally known that agents that are noninjurious to the cornea and conjunctiva of the rabbit are equally or even less irritating to that of the human eye, it may be concluded that streptomycin in concentrations of 10,000 mcgm. per ml. saline may be safely recommended for local application to the human eye. This has been proved subsequently by our clinical experiences with this antibiotic.

b. Effect of intraocular injection of streptomycin. As previously stated, even after huge systemic doses of streptomycin barely detectable amounts are found in the vitreous. It therefore follows that this method of administration would be in-

Fig. 2 (Bellows and Farmer). Abraded cornea receiving 50,000 mcgm. streptomycin per ml. saline.

effective except perhaps in infections with the most susceptible organisms. The present study was therefore undertaken to determine the tolerance of the ocular fluids and tissues to the direct injection of streptomycin. Also, to be determined was the length of time that an effective therapeutic concentration may be expected following a single intraocular injection.

For this study, solutions of various

commercial lots of streptomycin (HCl) and a highly purified sample of streptomycin-calcium-chloride complex, in concentrations ranging from 250 to 10,000 mcgm. per ml. were prepared in saline. The respective solutions in doses of 0.1 ml. were injected with a 27-gauge needle, making the puncture at the equator of the eyeball. Caution was practiced to deposit the streptomycin as near the center of the vitreous as possible. The eyes were ob-

ophthalmoscopically was damage to the retina observed. Histologic sections of several eyes examined by Dr. Bertha A. Klien failed to reveal any changes in the tissues in those eyes receiving the injection.

The studies of streptomycin retention in the vitreous revealed between 12.5 to 25 mcgm. of streptomycin even 24 hours after its injection. Thus after a single intraocular injection of 100 mcgm. of strep-

Fig. 3 (Bellows and Farmer). The picture at the left shows the vaccinia-keratitis infected control eye. At the right is the vaccinia-keratitis infected eye which has been treated with streptomycin.

served daily with the ophthalmoscope, checking with the slitlamp to confirm ophthalmoscopic observations. At varying intervals, the eyes were removed for histologic study.

For determining the retentive power of the vitreous for streptomycin, 100 mcgm. of the antibiotic in 0.1-ml. saline were injected into the vitreous in a series of rabbits. At specified intervals of 4, 8, and 24 hours the vitreous was removed and the streptomycin content determined.

The frequency and number of permanent vitreous opacities were low with the more purified commercial samples (21 eyes—6 opacities), and least with the highly purified streptomycin-calcium-chloride complex (19 eyes—4 opacities). In many instances the opacities were in the form of a "needle track" which gradually disappeared over a period of several weeks. An occasional posterior cortical or capsulo-cortical lens opacity appeared, which was attributable to trauma by the needle, or to the injection of the solution too close to the lens. In none of the animals where the fundus remained visible

tomycin, an adequate therapeutic concentration may be expected for over 24 hours.

It may be concluded that the purer commercial forms of streptomycin may safely be injected into the vitreous. The initial changes observed are in many instances transient, and will probably be less marked in the human eye because of its size. These findings are similar to those obtained by von Sallmann⁹ with penicillin. Therefore any theoretic objections to intra-vitreous injections of streptomycin in cases of infection of the vitreous with a sensitive organism are unfounded.

3. THE EFFECT OF STREPTOMYCIN ON VACCINIA KERATITIS

Our previous studies⁴ had demonstrated the value of streptomycin in certain ocular infections. The following experiments were undertaken to determine the value of streptomycin in experimental vaccinia infections of the cornea in rabbits, and to study its effect on the accompanying secondary infection.

In a series of normal rabbits anesthetized by intravenous injections of nembutal, an area of each cornea was outlined with a 4-mm. trephine. The epithelium within this area was abraded by a knife, following which a drop of vaccinia was placed on the abraded region and the eye was kept open for 60 seconds. Previous experiments had shown that uniform infections of the cornea were obtained by this means. One hour after the inoculation, drops of streptomycin (10,000 mcgm. per ml. saline solution) were instilled into the right eye. These instillations were made three times daily until the end of the experiment. Before the inoculation and every morning at the same hour before daily treatments were started (about 16 hours after the last streptomycin had been applied the previous day) a single platinum loopful of material was taken from each conjunctival sac and inoculated on blood agar. Twenty-four hours later organisms were identified and colonies were counted. The two main organisms were *Neisseria catarrhalis* and *Hemolytic staphylococcus albus*. The results of the bacteriologic observations showed that up to the sixth day no differences in the number and type of organisms were noted.

However, after this period the number of colonies from the treated eye was con-

sistently lower than in the control eye. As a result of the decreased amount of secondary infection in the treated eyes, the degree of scarring and vascularization in 80 percent of the corneas was much less marked than in the untreated eyes (fig. 3).

SUMMARY

The penetrability of the cornea to streptomycin may be increased by abrasion, inflammation, ion-transfer, and wetting agents.

Streptomycin is safe and nonirritating to the surface of the eyeball in concentrations up to 10,000 mcgm. per ml. Higher concentrations delay the regeneration of the epithelium and promote scarring and vascularization of the cornea.

Intravitreal injections of 500 mcgm. of streptomycin in 0.1-ml. saline are well tolerated.

The vitreous retains an effective therapeutic concentration for over 24 hours following the intraocular injection of 100 mcgm. of streptomycin.

Local application of streptomycin decreases the amount of secondary infection accompanying vaccinia infections of the cornea. As a result of this, there is less scarring and vascularization of the corneas of the treated eyes.

OPERATIVE TECHNIQUE OF VITREOUS REPLACEMENT*

MILO H. FRITZ, M.D., THERESA M. FENNESSY, R.N., AND HUGO CABRERA, A.B.
New York

The purpose of this paper is to present in detail the simple and nontraumatizing technique of substituting a given amount of a patient's clear cerebrospinal fluid for an equal amount of cloudy vitreous. In developing the technique, which any well-trained ophthalmologist will find easier than standard operations for cataract or filtration operations for glaucoma, the simplest manipulation with the least complicated instruments was constantly sought after. The development of expensive and complicated apparatus was carefully avoided. Full advantage was taken of the published work of earlier investigators^{1,2} on this problem, and of the cheerful generosity of the Research Department of Becton, Dickinson & Company, Inc., of Rutherford, New Jersey, who helped to develop and who supplied, gratis, the needles and syringes, which are the only special apparatus needed to perform this operation easily and successfully.

Using aseptic technique, a spinal tap is performed on the ward as short a time as possible before the operation. About 4 cc. of cerebrospinal fluid are collected in a dry, powder-free, cotton-stoppered, sterile test tube, which is carried directly to the operating room, where it is transferred into a sterile, dry, dust-free medicine glass on the instrument tray. Besides the ordinary instruments needed to perform an operation on the extraocular muscles, the following special items are required:

- 1 2-pronged corneal pick.
- 1 tube of 4-0 plain catgut on a cutting atraumatic needle.

1 tube of 4-0 black silk on a cutting atraumatic needle.

2 2½-cc. Luer-Lok syringes.†

2 Special 18-gauge needles with stylets.†

The pick is used to steady the globe when placing the purse-string suture of 4-0 plain catgut at the elected puncture site. The two special syringes are constructed with minimal clearance between plunger and syringe wall in order to avoid air leaks when suction on the vitreous is made, and the needles (fig. 1) have a sty-

Fig. 1 (Fritz, *et al.*). Two needles used in the substitution of cerebrospinal fluid for cloudy vitreous.

let to prevent loss of vitreous when puncture of the sclera is made. One type of needle is cut off at right angles to the shaft so that no point exists to injure the retina or the lens when the eye collapses as vitreous is withdrawn. There is a stop, 12 mm. from the end of the needle, to prevent too deep penetration of the needle into the vitreous chamber at the time of puncture.

Under pentothal sodium or local anesthesia, adrenalin (1:1,000) and pontocaine (0.5 percent) are applied to the eye topically. The eye speculum is inserted between the lids. A conjunctival incision is made parallel to and about 5 mm. from

* From the Eye-Bank for Sight Restoration, Inc. The expenses connected with this research were met by The Florence Ellsworth Wilson Memorial Fund Fellowship in Ophthalmology.

† Available upon special order from Becton, Dickinson & Company, Rutherford, New Jersey.

Fig. 2 (Fritz, *et al.*). The procedure is shown schematically as it is done on the left eye. A. With the eye speculum in place, the site of the conjunctival incision in the upper nasal quadrant is shown. B. The sclera is exposed and the conjunctiva has been retracted with a piece of 4-0 silk. The location of the puncture site is shown with a little cross. C. The three sides of the 1-mm. square of 4-0 plain catgut are shown placed in the sclera about the puncture site. D. The needle and stylet have been removed, the empty syringe has been inserted into the needle hub, and the cloudy vitreous spinal fluid has been substituted for that containing cloudy vitreous. A quantity of cerebrospinal fluid roughly equal to that of the aspirated vitreous has been injected into the vitreous chamber. Some cerebrospinal fluid remains in the syringe. The needle tip can be seen through the pupil in the centrally cleared vitreous. Tension of the eye is just a trifle harder than it was preoperatively as estimated by touching the globe with a squint hook. E. The 4-0 plain-catgut suture has been drawn up and tied as syringe and needle were withdrawn. The conjunctival incision has been closed with a running stitch of 4-0 silk.

the limbus. It is of sufficient length to allow easy access to that portion of the upper nasal quadrant of the sclera which is 12 mm. from the limbus. The assistant draws $2\frac{1}{2}$ cc. of the 4 cc. of cerebrospinal fluid previously obtained into one of the special syringes. While steadying the globe with the pick, three sides of a 1-mm. square of plain 4-0 catgut are placed at the chosen puncture site in the

sclera (fig. 2). When the two ends are tied, a purse string will result by completing the fourth side of the square. The two ends of the suture are then used to steady the globe with one hand, while the special needle with stylet is pushed through the sclera up to the stop. The puncture site is, of course, the center of the square outlined by the catgut suture. The stylet is then withdrawn from the

needle and the empty 2½-cc. special syringe is inserted into the hub of the needle which has already been inserted up to its stop in the vitreous chamber. Gentle suction is then produced carefully, moving the syringe and needle in and out and from side to side until from 1¼- to 2¼-cc. of cloudy vitreous are withdrawn. All the vitreous that can be withdrawn without undue suction or trauma is taken and the amount varies, for reasons as yet unknown, between the quantities mentioned. As the globe collapses like a punctured basketball, the needle is not allowed to penetrate more deeply, and the position of the intravitreal end of the needle in relation to the lens and retina opposite is constantly kept in mind.

The syringe containing 2½ cc. of cerebrospinal fluid is now substituted for the one containing all the vitreous that could be aspirated. The fluid is then gently injected into the eye, which assumes its normal shape. With the index finger on the plunger, to prevent regurgitation of fluid into the syringe, the tension of the globe is determined with a squint hook, and it will usually be found that the amount of cerebrospinal fluid injected roughly equals that of the vitreous withdrawn. An extra drop or two of fluid may be injected without harm, the eye being left a little harder, if anything, than is judged to be normal. The assistant then makes a half hitch in the purse string, and draws it up snugly about the needle shaft, whereupon needle and syringe are withdrawn from the vitreous chamber. The assistant then completes the knot on the purse-string suture. Before withdrawing the needle, a glance through the dilated pupil can reveal the needle point in the vitreous chamber. The conjunctiva is then closed with the 4-0 silk suture. A 1-per-cent atropine-sulphate ointment is placed in the conjunctiva, and a single eye patch is applied. If the operator wishes to do so,

an ophthalmoscopic examination may briefly be made and some idea of the ultimate result may be ascertained before ointment and dressing are applied.

COMMENT

In the development of this experiment, cerebrospinal fluid was considered ideal for several reasons. In the first place, it is easily available and doubtless has the same immunologic and other properties common to the body fluids of the individual patient. It is a substance more like vitreous than any other substance, with the exception of vitreous taken from a donor eye. Yet the properties of turgescence and deturgescence characteristic of a gel (and vitreous is considered to be one³) militate against the use of vitreous; whereas, cerebrospinal fluid being a sol does not change its volume. What happens to the mixture of cerebrospinal fluid and residual vitreous in the eye is as yet unknown.

Here at the Eye-Bank, the use of vitreous transplants (according to the method of Cutler⁴) from eyes enucleated elsewhere as donor eyes was considered. It has been found, however, that culture of the outside surface of such eyes⁵ often yields bacterial growth. The effectiveness of the sclera and cornea as barriers against bacterial contamination of the vitreous is unknown. It is known that the vitreous of living human eyes is an excellent culture medium for bacteria, hence it was not considered justifiable to inject vitreous of doubtful sterility into the eyes, even though partially blind, of living human beings.

Refrigerated human eyes were used in the development of the needles and syringes. It was found that no more than 2¼ cc. of vitreous could be withdrawn, without undue suction or trauma, from enucleated normal eyes from 12 to 72 hours after enucleation at temperatures

from 34° to 72°F. No retinal detachment or ectopia lentis, which could with certainty be blamed on the aspiration of vitreous, was ever seen in these eyes. For these reasons, cauterization about the puncture site of living eyes and complicated pieces of apparatus, which would allow simultaneous injection and withdrawal of vitreous to maintain intraocular tension constant, were deemed superfluous.

The stop was placed on the shaft to prevent too deep penetration of the needle and stylet at the time of puncture. However, it must be remembered that this stop does not prevent the likelihood of scraping the lens or opposite retina as the eye collapses, unless this danger is kept constantly in mind. So far this has not hap-

pened in the refrigerated or living eyes. In fact, as withdrawal and injection are done, the eye should be suspended from the needle, rather than being allowed to sink into the eye as it collapses.

The stylet was used to supply a cutting point and to prevent loss of vitreous before the syringe could be placed in the needle, and the elimination of the needle point was thought to lessen the danger to ocular structures.

It is hoped that this detailed report will encourage ophthalmologists with suitable cases to perform this useful operation in order that its true place in the treatment of certain ocular conditions may be determined.

BILATERAL GRANULOMATOUS UVEITIS FROM THE USE OF HORSE SERUM IN RABBITS*

T. F. SCHLAEGEL, JR., M.D.

Indianapolis, Indiana

This report concerns a continuation of studies on the reaction of the rabbit eye to horse serum. In 1943, Davis and I found a close resemblance to the histopathologic picture of sympathetic ophthalmia in rabbit eyes injected with normal horse serum, but there was no evidence of uveitis in the opposite eyes.¹ By the use of another method,² consisting of an intraocular injection followed by one intravenously, a slight choroidal infiltration was found in 40 percent of the uninjected eyes. The purpose of the present investigation was to see if this contralateral uveitis could be increased.

This production of a uveitis in the uninjected eyes calls attention to the problems of sympathetic ophthalmia and of bilateral granulomatous uveitis. Sympathetic ophthalmia has never been produced in animals despite numerous attempts, but it has been roughly simulated by a number of investigators. In 1918, Woods, using an emulsion of homologous uvea injected into one eye, followed later by an intraperitoneal shocking dose, produced a sympathizing reaction in the contralateral eyes of dogs consisting of a round-cell infiltration of the anterior uvea but without epithelioid or giant cells.³ In 1924, von Szily produced a bilateral intraocular inflammation with lymphocytes and epithelioid cells by inoculating the herpes virus into one eye only.⁴ In 1924 and 1925, Guillery introduced capsules containing tubercle bacilli into the vitre-

ous of one eye of rabbits and produced a bilateral uveitis resembling sympathetic ophthalmia.⁵

In 1929, Riehm concluded that horse serum absorbed from one eye produced an elective sensitivity in the fellow eye, resulting in uveitis after intravenous injections in pigmented rabbits but not in albinos.⁶ He did not subject the pigmented and albino rabbits to identical procedures and apparently did not make a histologic study. By using a larger number of rabbits, identical procedures, and histologic study, I demonstrated, in 1944, an equal reaction in the eyes of pigmented and albino rabbits after an intraocular followed by an intravenous injection of normal horse serum.²

In 1929, Marchesani reported a contralateral reaction from repeated injections of avirulent organisms into one eye of rabbits. He first used *Bacillus subtilis*⁷ and later *Bacillus xerosis* and *Staphylococcus albus*.⁸ The lesion consisted of loose, nodular accumulations of mononuclear cells of various types. Marchesani concluded that the contralateral response was due to uveal allergy, but an allergic basis was disputed by von Szily⁹ who showed that similar lesions could be produced by intravenous injections and by Iga who added that injections into an empty orbit would do the same.¹⁰

Friedenwald and Rones, in 1931, found essentially similar lesions in the human choroid as a result of septicemia and called this loose infiltration by mononuclear cells a "septic choroiditis."¹¹ Lucic, in 1939, used repeated intracutaneous injections of a combined culture of diphtheroids and a toxin-producing staphylococcus treated with tricresol to sensitize

a group of rabbits. As a result of subsequent intraocular, intravenous, and intracarotid injections of *B. hoffmannii*, a contralateral response with epithelioid cells, giant cells, and pigment phagocytosis developed in the contralateral eyes.¹²

PRELIMINARY INVESTIGATION

In a search for the most favorable conditions for a contralateral response, a group of 38 rabbits was used to determine whether 1 or 2 weeks between intraocular and intravenous injections was the best interval and whether doses of 5, 10, 20, or 30 cc. of horse serum intravenously gave the best response.

MATERIALS AND METHODS

Normal pigmented rabbits weighing from 4 to 7 pounds were examined with the aid of a flashlight, and those with diseased eyes were discarded. The right eyes were prepared with drops of 4-percent butyn and 1:1,000 merthiolate solution. The lids were opened manually by an assistant while a 25-gauge needle on a tuberculin syringe was used to make the intravitreal injection about 7 mm. behind the limbus in the 12-o'clock meridian. One-tenth of a cubic centimeter of sterile normal horse serum* preserved with 1:10,000 merthiolate was then injected. Most of this volume regurgitated leaving a subconjunctival bleb.

Both eyes were examined three times a week with flashlight and ophthalmoscope. After an interval of 1 or 2 weeks, an intravenous injection of either 5, 10, 20, or 30 cc. was given in the marginal ear vein. A week later the animals were killed by air embolism. The right eyes were subjected to six, and the left eyes to 12 scattered sections all stained with hematoxylin and eosin.

* Supplied by Eli Lilly and Company.

RESULTS

Almost immediately after the intravenous injections, some of the rabbits went into anaphylactic convulsions and died. Many developed body sway, vestibular nystagmus, and head tilt. Weakness was common, with a few dying during the next two days. Of the 38 rabbits, 28 survived until the proper time for enucleation. Microscopic study of this latter group indicated that about 80 percent of the uninjected left eyes developed a mild mononuclear infiltration of the uvea typical of mild reactions observed in injected eyes. It was found that the 2-week interval between intraocular and intravenous injection, and the 20-cc. dose were best for the production of a contralateral uveitis.

EXPERIMENT 1

Right intraocular injection followed by repeated intravenous injections. The right eyes were injected as before. Repeated intravenous injections were used; the first was delayed for three weeks and subsequent ones were given at intervals of one week. Thirty-seven rabbits were divided into three groups to be enucleated one week after 2, 3, or 4 weekly intravenous injections of 20 cc. of sterile normal horse serum. The eyes were prepared, injected, examined, sectioned, and stained in the same manner as in the preliminary investigation.

CLINICAL OBSERVATIONS

As a result of the repeated injections, only 12 of the 37 rabbits lived to the time for enucleation. In Figure 1 the reactions in the anterior ocular segment are plotted to demonstrate the average severity of the reaction on each day of the experiment. The reactions were graded from 0 to 4. Plus 1 indicates a slight conjunctival injection; plus 2, moderate bulbar congest-

tion and slight iritis; plus 3, conjunctival chemosis, pronounced bulbar congestion, and moderate iritis; plus 4, extreme chemosis and bulbar congestion, with strands of exudate over iris and pupil. Because the bulbar congestion almost disappeared during the later stages of the experiment, these criteria were varied for the later stages to include other signs such as a capsular clouding of the lens, haziness of the cornea, corneal vascularization, and keratectasia.

The clinical course can be described best by considering the periods between injections.

Features during the three weeks prior to intravenous injections

Right eyes. Following the injection into the right eyes, there was only a minimal reaction consisting of a slight circumcorneal hyperemia and a hazy vitreous in one fourth of the cases. At the end of five days this haze had increased until the visibility of the fundus was poor. The retinal vessels often were dilated. On the ninth day the reaction in the right eyes was pronounced and was rated at plus 2 or plus 3 in many of the rabbits. Fibrinous and cellular exudates were common on the irides and on the anterior lens capsules. Thereafter the fundi of the right eyes in most cases could not be visualized because of cloudy vitreous and anterior capsular opacities. When the fundi could be seen, vitreous veils were common, especially in the region of the retinal vessels. By the end of this 3-week period most of the bulbar congestion had disappeared, but some eyes with keratectasia were graded plus 3.

Left eyes. No reaction was observed for about two weeks. Then a mild dilatation of the retinal arteries and veins appeared.

Features during the week following the first intravenous injection

Right eyes. The reactions in the anterior ocular segment were again pronounced and more severe than before, usually plus 3 or plus 4.

Left eyes. Some of the left eyes began to present mild evidence of reaction, such

Fig. 1 (Schlaegel). The average intensity of reaction in the anterior ocular segment in right and left eyes of Experiment 1 and both eyes of Experiment 2 plotted against the time interval in days.

as slight circumcorneal injection and slight signs of iritis. In one case spots of cellular exudate were found on the anterior lens capsule. The severity of the reaction increased gradually during this week and a pronounced vitreous veil developed in one eye.

Features following second intravenous injection

Right eyes. There was a slight peaking of the response and then a gradual decline due to lessening of congestion.

Left eyes. The reaction remained roughly constant. There was nothing remarkable about the fundi until three days later when choroidal exudates developed along the retinal vessels and in the periphery along with haziness of the vitreous.

Features following third intravenous injection

Right eyes. Again there was only a slight congestive response with a subsequent decline of the degree of hyperemia. Two of the right eyes had generalized corneal relucence; one case developed *occlusio pupillae*, and another, corneal vascularization.

Left eyes. All left eyes were involved. In two thirds of them choroidal exudates were seen.

Features following fourth intravenous injection

Right eyes. The reaction was less than before with a continued abatement of congestion.

Left eyes. Engorgement and tortuosity of the veins and a haziness of the disc were prominent findings. The choroidal exudates were still visible.

EXPERIMENT 2

Intracutaneous injection followed by repeated intravenous injections. In an attempt to elucidate the mechanism of the contralateral ocular response of the first experiment a group of 16 rabbits were each given an intracutaneous injection instead of a right intraocular injection. One tenth of a cc. of sterile normal horse serum preserved with merthiolate was injected into the epidermis producing a distinct bleb. Otherwise these rabbits were treated as in the first experiment.

CLINICAL OBSERVATIONS

In Figure 1, it can be seen that the average response in the anterior ocular segment shows a peaking in the intensity of the reaction after each intravenous injection, but that the general sweep of the reaction did not reach the intensity of the left or contralateral eyes in the first experiment.

After the first intravenous injection the

retinal vessels appeared slightly dilated and tortuous. Choroidal exudates along the retinal vessels and in the periphery, haziness of the media, and haziness and hyperemia of the disc appeared during the following days. In general, the fundus picture was very similar to that in the uninjected eyes of the main experiment except that it was not as frequently seen nor as pronounced in development.

Figure 1 demonstrates that a pronounced reaction was present in the injected right eyes nine days after the intraocular injection of horse serum. Appreciable reactions appeared in the left or contralateral eyes around nine days after the intravenous injections were begun, while the curve of the intracutaneous group shows only slight peaking after each one. Figure 1 also indicates, especially in the injected eyes, a decline in the intensity of the reactions in the anterior ocular segment after the later intravenous injections. This phenomenon may be due to desensitization as a result of the large doses of serum.¹³

In Table 1, the clinical features of the three groups are summarized.

In addition to 12 scattered sections of both right and left eyes of the intracutaneous group, sections of muscle, liver, kidney, lymph nodes, spleen, lung, heart, and small and large intestine were obtained to see whether the horse serum produced a generalized response. A minimal reaction was found only in the myocardium and kidney, consisting of small accumulations of mononuclear cells. This minimal infiltration is of little significance because it may have been caused by other factors.

OCULAR HISTOPATHOLOGY

In all three groups the choroid is the tissue most involved. There is only slight infiltration of the anterior uvea.

Injected eyes. Eye sections of rabbits

Fig. 2 (Schlaegel). Injected eye of a rabbit which died immediately after the second intravenous injection. The choroid has been increased to 20 times its normal thickness. There is an extension of the infiltration into the inner lamellae of the sclera.

which died early show the choroid of injected eyes to be heavily infiltrated with pale areas of epithelioid and occasional giant cells in no definite arrangement, lying in a darker field of lymphocytes,

plasma cells, and large mononuclears (fig. 2). After 5 to 7 weeks the cellular infiltration is being replaced by fibrous tissue (fig. 3). This fibrosis involves both the retina and choroid. In one eye in which there was a tremendous thickening of the

former retina by heavy fibrous tissue, the use of special stains, including phospho-

tungstic acid hematoxylin, demonstrated an absence of gliosis.

One of the severely reacting injected eyes will be described. It was the only case sectioned that showed appreciable corneal changes.

Description of one injected eye

Mononuclears, especially plasma cells, are found between the lamellae of the anterior two thirds of the cornea. Capillary loops extend to near the center of the cornea in the infiltrated region. A heavy collection of mononuclear cells is found superficially at the limbus. In its posterior portion, the iris is mildly infiltrated mainly with plasma cells. A heavy fibrous cyclitic membrane stretches out from the

ciliary body and extends behind the lens. The retina and choroid have been converted into one common membrane. The retina is necrotic and no longer recognizable. It is mildly infiltrated by extension from the choroid. The choroidal infiltration, consisting mainly of plasma

of the choroidal infiltration back along the leptomeninges.

Contralateral eyes. In the uninjected left eyes of Experiment 1, microscopic study reveals cellular infiltration in every case. Although the degree of cellular infiltration is greater than in a previous experiment² and in the preliminary test of this investigation, it is not as severe as in the injected eyes (table 3). This contralateral infiltration consists of large mononuclears, lymphocytes, plasma cells, and epithelioid cells bulging the choroid up to five times its normal thickness (fig. 5). No giant cells or large epithelioid cell aggregates were produced.

Description of one contralateral eye
There is a mild mononuclear infiltration in the superficial tissues at the limbus. There is only a minimal infiltration of the posterior half of the iris, the choroid being the tissue most involved. This choroidal infiltration is diffuse with nodular bulgings. It has caused a mild infiltration of the inner lamellae of the sclera, and a mantle around the perforating vessels. There are a few collections of cells in the orbital tissues. The ciliary body is mildly involved in its inner and posterior portions. The cornea, retina, pigment epithelium, and optic nerve remain uninvolved.

Three main features serve to differentiate the injected response from that in the contralateral eyes: (1) Heavier cellular infiltration. (2) Distortion, necrosis, and infiltration of the retina. (3) Replacement fibrosis.

Eyes of the group sensitized by intracutaneous injection. In some of the eyes the choroidal infiltration is so slight that it is difficult to tell whether wandering cells are present. The choroid is the only tissue involved. There is only a minimal diffuse infiltration of lymphocytes and large mononuclear phagocytes. Plasma

cells has become somewhat thinned out and the fibrous tissue more abundant. The cells from the choroid have extended into the inner lamellae of the sclera and they form a mantle around the perforating vessels. The orbital tissues are involved by the same type of cells (fig. 4). At the optic disc the nerve and its septa are mildly involved and there is an extension

cells and epithelioid cells are seldom seen. The impression gained is that of a mild replica of the reaction in the other two groups.

In Table 2, the histopathologic features of the three groups are outlined. In Table 3 is shown the degree of histopathologic response in each eye sectioned. This table clearly demonstrates a severe reaction in the injected eyes, a moderate response in the contralateral eyes, and a minimal reaction in the eyes of the intracutaneous group. It also shows that there is no significant difference between the reactions when 2, 3, or 4 intravenous injections were used. Replacement fibrosis in injected eyes, however, was more common and prominent after the longer intervals. The criteria for the grading of the histopathologic response are as follows: Plus 1, minimal uveal infiltration by lymphocytes and large mononuclears; plus 2, the infiltration including plasma and epithelioid cells fills the whole thickness of the choroid; plus 3, moderate distension of the choroid by the infiltration; plus 4, pronounced distension of the choroid by an infiltration which includes giant cells.

CONTROLS

Two minor controls were negative.

1. *Twenty normal* rabbit eyes were sectioned to determine the amount and type of cells normally found in the rabbit uvea. Each eye was subjected to six scattered sections stained with hematoxylin and eosin. The thinness and compact structure of the choroid was a striking feature. There was no evidence of wandering cells in the choroid of any of these eyes, but in the irides, plasma cells were common in the posterior one third of a few sections.

A study of these normal control eyes confirmed the reality of the cellular infiltration in the uninjected eyes of Experiments 1 and 2.

2. *To check on* the possibility that the merthiolate preservative in the horse serum played a role in the histopathologic response, a group of seven rabbits were each given a right intraocular injection of 0.1 cc. of 1:10,000 solution of merthiolate. (This solution was made roughly isotonic by mixing one part of a 1:1,000 solution of merthiolate with nine parts of sterile normal saline.) The right eye of one of these rabbits was enucleated each week and subjected to three scattered sections. Upon microscopic study no lesions were noticed, so it may be concluded that the merthiolate played no direct role in the production of the histopathologic picture.

COMMENT

1. LOCALIZATION OF THE CELLULAR REACTION IN THE UVEA

A striking characteristic of the reaction of the rabbit eye to horse serum is the localization of the cellular infiltration in the uveal tract. In the injected eyes there is no infiltration into the retina until it has become completely disorganized and the membrane of Bruch largely destroyed. In the uninjected eyes the retinas are unaffected and involvement of the sclera appears to be due to direct extension from the choroid. One might expect the uvea to be the site of predilection after intravenous horse serum because of its rich vascular character, but the uvea is also the site of predilection after a single injection into the vitreous. This uveal reaction is not explained by the studies of Thompson, Gallardo, and Khorazo who found no precipitins in the retina and choroid following intravenous egg albumin.¹⁴ The greatest precipitin concentration was found in the corneal-tissue juice. Although several injected eyes of the present experiment developed vascularization of the cornea, such a reaction was unusual while the uvea was involved in every case.

This predilection of cellular infiltration for the uveal tract is not confined to the effects of horse serum. It has been demonstrated over a period of many years by numerous investigators using various substances. Marchesani, for example, described, after repeated injections of avirulent organisms into one eye, a reaction in the choroid of the contralateral eyes that apparently would be hard to differentiate from the effects of horse se-

ferences in the cellular infiltration among the three groups (injected, contralateral, and intracutaneous) seem to depend entirely upon the differences in the severity and duration of the response.

A. Correlation of duration of reaction with types of cells. In 1943 we demonstrated that 12 hours after the eye of a previously sensitized rabbit is injected with horse serum the cellular infiltration is composed solely of polymorphonuclear

TABLE 4

STATISTICAL COMPARISON OF THE CLINICAL REACTIONS IN THE ANTERIOR OCULAR SEGMENT OF THE UNINJECTED EYES OF EXPERIMENT 1 (FIRST INJECTIONS IN RIGHT EYES) AND OF EXPERIMENT 2 (FIRST INJECTIONS IN SKIN) ON THE DAYS FOLLOWING THE LAST THREE INTRAVENOUS INJECTIONS

	Exp. 1 (Left Eyes)	Exp. 2 (Both Eyes)	Exp. 1 (Left Eyes)	Exp. 2 (Both Eyes)	Exp. 1 (Left Eyes)	Exp. 2 (Both Eyes)

rum.^{7, 8} This similarly brings up the possibility of contamination of the horse serum used in my experiments. However, it was received in a sterile condition preserved with merthiolate. It was handled with aseptic technique, and aerobic and anaerobic cultures of samples during the course of the experiment failed to grow any organism. If any surgical contamination occurred, it was in all likelihood so slight that the rabbits' natural defenses were protective. This supposition is supported by the fact that in no instance has a rabbit eye injected with horse serum ever demonstrated any sign of purulent inflammation.

2. CHARACTER OF THE CELLULAR REACTION

The qualitative and quantitative dif-

ferences in the cellular infiltration among the three groups (injected, contralateral, and intracutaneous) seem to depend entirely upon the differences in the severity and duration of the response.

In some granulomatous diseases, especially tuberculosis, a similar sequence takes place, the dominant cell varying with the age of the lesion. Early there are polymorphonuclear leukocytes; later the mononuclear cell and lymphocyte are dominant; and still later giant cells and epithelioid cells are common.

B. The possible role of lipids. Sabin, Doan, and Forkner have shown that lipids from tubercle bacilli act as maturation factors for monocytes or large mononuclear phagocytes, converting them into epithelioid cells and epithelioid cells into

Langhans giant cells.¹⁵ Also, lipid extracts from pyogenic bacteria, such as the colon bacillus, will give rise to epithelioid and giant cells.¹⁶ In the case of horse serum the granulomatous response may be due to the lipid degradation products of horse serum broken down by an antigen-antibody reaction or by tissue lipases. Or it is possible that the response may be due to lipids set free from the uveal tissues themselves.

The presence of lipids in bacteria and in body tissues may explain why similar granulomatous responses have been obtained from a variety of different agents.

3. IS THE CONTRALATERAL RESPONSE RELATED TO AN INCREASED QUANTITY OF HORSE SERUM ENTERING THAT EYE?

The eyes contralateral to those injected developed a significantly greater clinical and microscopic reaction than the eyes of rabbits sensitized by intracutaneous injection. The histopathologic reaction was twice as great. This difference is obvious upon examination of the microscopic slides and was found to be statistically reliable in computation of the probable error of the gradings.

The clinical reaction was also roughly twice as great in the contralateral eyes. In Table 4 the figures for the peak reactions following the last three intravenous injections are given. It can be seen that the average reactions on these specified days are statistically different as far as can be determined in a clinical investigation of this sort.

These results may be explained partially by the work of Guy who found that the following procedures would facilitate the passage of horse serum into the anterior chambers of both eyes: (1) An injection of horse serum into the anterior chamber of one eye. (2) Repeated intravenous injections. (3) Large intravenous injections.¹⁷

In the present experiments, including the preliminary tests, a greater reaction was obtained: (1) When one eye instead of the skin was injected. (2) When two or more intravenous injections were used. (3) When the intravenous doses were large.

These findings parallel and confirm those of Guy. Since he found that such procedures increased the penetration of horse serum into the contralateral eyes, it may be that a greater penetration was the cause of the more pronounced reaction in the uninjected eyes of Experiment 1 as compared to those of Experiment 2. The reasons for this assumed greater penetration were not learned, but there are at least two possibilities which should be considered.

1. A dilatation of the retinal arteries and veins was observed in the contralateral eyes two weeks after the intraocular injection. A similar vasodilatation in the uveal tract might result in an increased transudation of horse serum from the blood stream. In the group sensitized by the intracutaneous route such a retinal vasodilatation was not found prior to the intravenous injections.

2. A second possibility is that the eye is superior to the skin as a site for general sensitization of the rabbit. In a rabbit with a greater degree of general sensitivity, it is possible that transudation of horse serum into an uninjected eye might be increased or that once present its ability to incite a response is enhanced. However, this supposition of greater general sensitivity is not very well substantiated by a comparison of the number of rabbits dying of anaphylaxis in each group. In the first experiment 68 percent, and in the second, 57 percent, died as a result of the intravenous serum. This difference is hardly significant, indicating that roughly the same degree of sensitivity developed in both groups.

4. COMPARISON WITH SOME CLINICAL TYPES OF GRANULOMATOUS UVEITIS

The clinical reactions in the anterior ocular segment were not typically granulomatous in type due mainly to minimal iris involvement and to the presence of an anaphylactic congestive phase. The histologic reaction was more obviously of a granulomatous character and it is this histologic picture which will be compared to some of the clinical types of granulomatous uveitis.

A. Sympathetic ophthalmia. The histopathologic features of the reaction of the rabbit eye to normal horse serum, as compared to the features of sympathetic ophthalmia, were covered in previous reports.^{1, 2} The features obtained in those studies were more typical of sympathetic ophthalmia than the ones obtained in this experiment.

With the later enucleations and larger doses used in this experiment, absorption of the infiltrate, fibrosis, and severe retinal necrosis were found in the injected eyes. Another feature of sympathetic ophthalmia has been simulated, however, and that is the production of an appreciable contralateral granulomatous uveitis.

Despite the similarity of the response to sympathetic ophthalmia there are two main points of difference.

1. First and foremost is the distortion, necrosis, and infiltration of the retinas in severely reacting injected eyes.

2. Second is the lesser degree of pigment phagocytosis.

B. Syphilitic uveitis. Except for the absence of perivascular infiltration and obliterating endarteritis, the reaction of the rabbit eye to horse serum bears a resemblance to a syphilitic uveitis. The same types of cells are present; the pigment epithelium is often destroyed; the retina is involved; and the infiltration is followed by organization.

C. Tuberculous uveitis. Characteristic

features of tuberculous uveitis such as nodular infiltration, caseation necrosis, and anterior iris nodules, are not present in the reaction to horse serum, although some of the less distinctive features are seen.

D. Uveitis due to sarcoidosis. The main points of difference are that in sarcoidosis the anterior uvea is usually more affected than the posterior part, and the lesions disappear with little scarring. The main points of similarity lie in the presence of tuberclelike masses of epithelioid cells in injected eyes, and in the absence of caseation necrosis.

SUMMARY

When the right eyes of rabbits were injected with normal horse serum and the rabbits were later given repeated large doses intravenously, a bilateral granulomatous uveitis developed in every case. The reaction was severe in the injected eyes and moderate in the uninjected. The tissue response consisted of an infiltration of the uvea by lymphocytes, large mononuclear phagocytes, plasma cells, and epithelioid cells. The injected eyes developed replacement fibrosis and involvement of the retinas; whereas, the infiltration in the uninjected eyes remained fresh and the retinas were not affected.

A second experiment was done in an attempt to elucidate the mechanism of the contralateral response. The rabbits of this second experiment received an original intracutaneous injection instead of a right intraocular injection but were otherwise treated in the same manner. It was found that both the clinical and microscopic reactions in the uninjected eyes of the first experiment were significantly greater than the reactions in the uninjected eyes of the second. The cause of this apparent superiority of the eye over the skin for the predisposition to a reaction in uninjected eyes was not learned.

STIMULATION OF CORNEAL EPITHELIZATION WITH TOPICAL APPLICATION OF ERYTHROCYTES*

AN EXPERIMENTAL STUDY

FRANK W. NEWELL, M.D.

Chicago, Illinois

A variety of chemical and physical agents has been recommended for topical application to stimulate wound repair but, after brief enthusiasm, almost all have been discarded as lacking the healing powers attributed to them. Hence it is with considerable diffidence that a report concerning yet another topical medication is submitted; however, compounds that accelerate the rate of corneal epithelization in experimental animals have been rarely reported and it is possible that local application of erythrocytes may have application in clinical ophthalmology.

Arey¹ in his comprehensive review of factors effecting wound healing mentions the following compounds reported at one time or another as stimulants to cell repair when applied locally. Vitamins A, C, and D, ergosterol and viosterol, testes pulp, thyroid, parathyroid extract, pancreas, insulin, suprarenal gland, anterior pituitary extract, leukocytes, embryonic tissue extract, Witte's peptone, and even irritants such as turpentine. Good results have been claimed for such physical agents as mechanical pressure, infrared, ultraviolet, and roentgen rays, phosphorescent light, and high-frequency electrical current. Hammett's² observation of the stimulating properties of certain compounds containing the sulfhydryl radical prompted reports on the beneficial effect of thiocresol,³ cysteine,⁴ glutathione,⁵ and more recently a proprietary preparation

"sulfhydryl solution."⁶ Šperti⁷ and his associates claim that "wound hormones," namely growth-stimulating substances released by damaged cells, initiate wound regeneration and accelerate healing. Recent well-controlled studies by Smith and Livingston⁸ have indicated a stimulative factor in water-soluble chlorophyll preparations, while Werner⁹ has used a heart extract in a large number of clinical cases with encouraging results. Marshak and Walker¹⁰ have used a chromatin derivative extracted from rat liver to cause increased rates of healing of skin wounds of rats. Schaeffer¹¹ observed an increased rate of epithelization in experimentally abraded corneas treated with a buffered solution containing the amino acids, cysteine, proline, asparagine, and glutamine.

The multiplicity of compounds recommended for acceleration of wound healing indicates the chaotic state of the literature and one must consider with caution the claims advanced by frequently over-enthusiastic investigators. In many of the earlier discussions, conclusions are founded on encouraging responses of the wounds to test agents as contrasted with the effects of medication used previously or after resistance to healing. Agents capable of stimulating tissue growth in culture or in experimental animals may have no similar action when applied locally in man. The cornea presents a singular problem in this regard as results derived from observation of skin healing cannot be applied in toto to corneal epithelization. In skin, wound repair is frequently by fibroblastic proliferation only; while in the cornea, restoration of normal epi-

* Read at the 16th scientific meeting of the Association for Research in Ophthalmology, Atlantic City, June 10, 1947. From the Department of Ophthalmology, Northwestern University Medical School. This investigation was supported in part by a grant from the Sanford R. Gifford Memorial Fund.

thelium is paramount and fibrous tissue formation is highly undesirable.

Moorhead and Unger¹² first employed concentrated human red blood cells as a wound dressing in 1943 and observed beneficial results in burns, infected and noninfected wounds, and certain types of ulceration. They suggested that erythrocytes might serve a useful purpose as a wound dressing in "raw and potentially infected surfaces." Seldon¹³ and his associates found that local application of red blood cells stimulated healing in approximately one half of the cases of chronic ulcers. They recommended its use in ischemic ulcers and those associated with venous stasis. A number of other investigators have confirmed the initial report, but Naide,¹⁴ after using whole blood, discontinued the use of erythrocytes believing that the plasma was more efficacious.

EXPERIMENT 1

This investigation was made to determine the effect of local application of concentrated, washed, human, red blood cells on experimentally produced corneal abrasions.

TECHNIQUE

Freshly drawn citrated, human blood was centrifuged immediately following withdrawal and the supernatant plasma and buffy coat layer containing platelets and leukocytes was removed. The remaining erythrocytes were then washed four times with five times their volume of normal saline to insure removal of all plasma. After removal of the saline and concentration of the erythrocytes by centrifuging, the red blood cell count was 8 to 9 million per cubic millimeter. The test ointment was made by blending 5 cc. of the concentrated erythrocytes in 5 gm. of Hydrosorb ointment (Abbott*). This

* A mixture of the oleic acid ester and the amide of diethanolamine in white petrolatum.

base was selected because of its lack of inhibition on the healing of the cornea as demonstrated by Smelser.¹⁵

Twenty-five immature, male, healthy guinea pigs weighing between 250 and 300 gm. were used. The animals were anesthetized with ether and a local ½-percent pontocaine solution. Using sterile precautions, the epithelium of a central corneal area, 4 mm. in diameter, in each eye was removed with a spatula.

Ointments were instilled in each eye four times daily at 8 A.M., 12 noon, 4 P.M., and 8 P.M. The erythrocyte ointment was used in the right eye, and the ointment base only in the left eye. Prior to the instillation of ointment, one drop of 2-percent fluorescein solution was placed in each eye and the eye was studied in intense illumination with a loupe. Healing was considered complete when the cornea did not stain.

RESULTS

Eight of the 25 animals used were discarded because of corneal infection and were not considered in the final results. Of the remaining animals, the average healing time of the right, treated eye was 36.1 hours with a minimum of 23 hours and a maximum of 44 hours. In the left eye, the average healing time was 48.2 hours with extremes of 28 and 70 hours.

Analysis† of the results indicated that the acceleration of healing in the treated eye was statistically significant. It was concluded that local application of an ointment containing human erythrocytes

† To determine if the difference between the mean healing time of the two eyes was significant or due to chance, the standard deviation of the theoretical distribution of differences between the right and the left eye was determined. It was found that a difference as large as 8.8 hours (3 standard errors of the difference between the two means) might arise due to chance. In that the observed difference was 12.1 hours, it was concluded that the results were significant.

stimulated corneal epithelization in the guinea pig.

The method by which red blood cells exert this action is not known, but the complex physical and chemical structure of the erythrocyte and the unique metabolism of the cornea gives basis for wide speculation. Many of the compounds reported to stimulate healing of skin wounds are present in the erythrocyte. Thus, all of the glutathione in blood is present in the red blood cell and Kendall¹⁶ was of the opinion that some chemical factor, possibly glutathione, was responsible for the effect. However, glutathione in 5-percent concentration in an ointment base does not stimulate corneal regeneration following abrasion in the guinea pig.¹⁷

Globin and ghost cells contain all of the essential amino acids and Murray and Shaar¹⁸ suggested, on the basis of their clinical investigation, that erythrocytes might supply nutritional elements, possibly deficient because of inadequate circulation. They also suggested that the crust of erythrocytes served as a mechanical scaffolding to support epithelization. Heme, the iron prosthetic group of hemoglobin, is a ferriprophoryn chemically related to chlorophyll and other porphoryns which have been reported to accelerate healing. All of the amino acids used by Schaeffer¹¹ to accelerate corneal epithelization are present in the red blood cell but as polypeptides and proteins and presumably not available for use as such.

Baker¹⁹ found that hemoglobin added to a mixture of liver ash and glutathione caused rapid proliferation of fibroblasts *in vitro*. She attributed this result to regulation of the oxidation-reduction reactions and respiration within the cells of the culture, and it is considered possible that a similar mechanism is responsible for acceleration of corneal healing activities.

Several investigators have attributed the healing action of erythrocytes, as observed in the treatment of stasis ulcers, to mechanical protection only. In that each eye in these experiments had comparable protection from the ointment base, it is concluded that such a factor is not responsible for acceleration of corneal epithelization in the eye. Carrell²⁰ showed that mild irritation of a wound initiated tissue regeneration while in the absence of chemical, mechanical, or bacterial irritation, healing was markedly delayed. However, sufficient irritation is ordinarily present in ocular wounds to initiate tissue regeneration and this mechanism seems highly improbable.

EXPERIMENT 2

To determine if a particular portion of the erythrocyte was responsible for the stimulation, an investigation was made using the primary products of mechanical and chemical fractionation of the erythrocyte; that is ghost cells, globin, heme, and hemoglobin.

TECHNIQUE

Whole citrated blood, 10 to 15 days old, obtained from the Wesley Memorial Hospital Blood Bank, was used in all procedures. All manipulations, including centrifuging, were carried out at a temperature of 2°C., except as noted. The erythrocytes were separated from the plasma and washed five times with normal saline and refrigerated until used.

Ghost cells, the cell envelopes of the red blood cell with the hemoglobin removed, were obtained by adding to the washed erythrocytes five times their volume of water, saturated with carbon dioxide at 2°C. This hemolyzed and flocculated the cells which were then removed from the solution by centrifuging. The ghost cells were washed repeatedly with

cold, carbonated water until they assumed a light, pinkish color and the supernatant fluid was colorless. An ointment was made by blending 5 cc. of the concentrated ghost cells with 5 gm. of hydrosorb ointment.

Oxyhemoglobin was prepared by the method of Marshall and Welker,²¹ first laking the washed erythrocytes with distilled water, mixing with freshly prepared alumina cream, and filtering in the refrigerator. The solution was sterilized by passage through a Berkefeld filter, and a test ointment was made by adding 5 cc. of the oxyhemoglobin solution to 3 gm. of ointment.

Globin and heme were prepared by the method of Anson and Mirsky.²² Oxyhemoglobin was prepared as above and cold, distilled water added to 10 percent of its volume. To this solution was added an equal volume of 0.1 N. hydrochloric acid. The globin was precipitated by adding 20 times the volume of acid acetone and then separated from solution by filtration and dried in air. The globin was dissolved in distilled water, sterilized by passage through a Berkefeld filter, and an ointment prepared of equal parts saturated globin solution and hydrosorb.

Heme was precipitated from the acid acetone filtrate by acidifying with sodium acetate. It was then separated from solution by filtration. It was dissolved in bicarbonate buffer (pH = 10.1), sterilized, and blended into an equal amount of hydrosorb.

Five male, albino rabbits weighing between 2 and 3 kilograms each were used to test each ointment. Following ether anesthesia, the corneal epithelium of each eye was removed with dry gauze, and the eyes were stained with fluorescein to assure equal removal. Ointments were instilled four times daily, the test ointment in the right eye and the ointment base

only in the left eye. Each cornea was stained with fluorescein prior to each installation of ointment, and the eye was studied in intense illumination with a loupe.

RESULTS

Healing time in the treated and untreated eyes was between 4 and 6 days with no significant difference in the rate of healing of the eyes treated with ointments containing respectively globin, heme, oxyhemoglobin, and ghost cells, and the control eyes.

The failure of these erythrocyte products to accelerate healing may be explained in a number of ways. The initial possibility was that the stored blood used to prepare these products had lost some factor present in freshly drawn blood which was responsible for acceleration of wound healing. It was possible, however, to accelerate corneal regeneration using stored erythrocytes which indicated that living cells were not essential.

It seems most likely that the substance or substances responsible for the stimulation of healing were so modified in the separation process as to lose this power or were entirely removed and not represented in the final product. On the basis of these experiments, it seems probable that the proteins of globin and ghost cells are not responsible for stimulation of healing, and that the porphoryn radical of heme has no such action. Not disproved is the possibility of a synergistic mechanism whereby these substances exert a stimulative action when combined and not when separated.

Certain of the compounds removed in fractionation of the erythrocyte may be responsible for the acceleration of wound healing. Caspe²³ suggested that allantoin is responsible, but this compound seems more likely an end product of metabolism

rather than possessing metabolic activity. The erythrocyte contains a relatively large amount of adenosine triphosphate which may furnish the high energy phosphate bonds necessary for increased corneal metabolism accompanying acceleration of healing. The potassium ion in the red blood cell could catalyze such an action. Coenzyme II which is present in significant amounts in the blood cell may catalyze the above action or one of several others all of which would increase corneal metabolism.

SUMMARY

Treatment of experimentally abraded corneas with an ointment containing washed, packed, human, red blood cells resulted in significantly increased rates of epithelization in the guinea pig.

Treatment with ointments containing ghost cells, heme, globin, and oxyhemoglobin, respectively, did not cause acceleration of corneal epithelization.

Possible mechanisms of this action are discussed.

DISCUSSION

DR. JONAS FRIEDENWALD (Baltimore, Maryland): I would like to ask what was the healing in eyes that were not treated at all, with any ointment. The question is asked because practically every ointment used in the eye delays healing to some extent, and I am wondering whether the favorable effect of the inclusion of red

blood cells in the ointment might merely be neutralizing the inhibition of the ointment.

DR. FRANK W. NEWELL (Chicago, Illinois): I have not conducted experiments on eyes treated without ointments. I am afraid that I am not able to answer that question.

THE EFFECT OF DI-ISOPROPYL FLUOROPHOSPHATE ON THE CAPILLARIES OF THE ANTERIOR SEGMENT OF THE EYE IN RABBITS*

LUDWIG VON SALLMANN, M.D., AND BEATRICE DILLON, M.A.
New York

The instillation of a 0.2-percent solution of di-isopropyl fluorophosphate into the conjunctival sac is usually followed in rabbits by a pronounced rise of ocular tension accompanied by edema of the ciliary processes and the formation of plasmod aqueous. These changes indicate increased capillary permeability correlated with elevation of intraocular pressure. In the present study on the mechanics of this transient experimental glaucoma, the functional alterations of blood capillaries in respect to permeability[†] were investigated, as well as the prevention of these alterations by several groups of drugs. The occasional rise of tension in human eyes after topical use of D.F.P.[‡] and especially the similarity of the test lesion to the human permeability glaucoma, added interest to the subject. Several aspects of the problem were examined using the rabbit as the experimental animal.

* Supported by the Knapp Memorial Foundation. From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, and the Institute of Ophthalmology, Presbyterian Hospital. Read in part at the 16th scientific meeting of the Association for Research in Ophthalmology, Inc., at Atlantic City, June 10, 1947.

† The term capillary permeability is used in the present study irrespective of whether the changes in the rate of diffusion across the capillary wall were the result of altered pore size in the intercellular cement or of increase in filtration pressure.

‡ In a group of 50 glaucoma patients observed in the Institute of Ophthalmology, Presbyterian Hospital, five eyes with primary glaucoma responded to the use of D.F.P. with an increase instead of with the expected decrease in intraocular pressure. Leopold and Comroe¹ and McDonald² have previously reported a smaller incidence of such a reaction in a much larger series of glaucomatous eyes treated with D.F.P.

EXPERIMENTAL PROCEDURES

The rise of ocular tension, the protein content in the aqueous, and the depth of the anterior chamber after the local use of D.F.P.

The histologic appearance of the anterior segment of the eye under the influence of D.F.P. as described by R. O. Scholz³ was confirmed in the present experiments. The changes consisted of swelling of the ciliary processes, development of Greeff blebs and appearance of a protein coagulate in the posterior and anterior chamber with some coating by proteins in the angle meshwork. They were especially striking when the eyes with heightened intraocular pressure after D.F.P. administration were compared to the untreated control eyes. Therefore, the relationship between protein content in the aqueous and the rise in tension was studied first.

TECHNIQUE

After tonometric determination of the ocular tension, 2 drops of an 0.2-percent solution of D.F.P. in peanut oil were deposited three times, three minutes apart, in the right eyes of adult chinchilla or albino rabbits. The changes in tension were recorded over periods of time from $\frac{1}{2}$ to 5 hours and sometimes up to 24 hours. Many experiments were terminated after one hour by withdrawal of aqueous from the treated and the control eyes for protein determination by the Looney-Walsh method adapted for 0.1 cc. of aqueous as previously described.^{4, 5} In a small number of experiments, the measuring of protein content was omitted.

These eyes were quickly frozen and cut in the vertical meridian and the depth of the anterior chamber in treated and control eyes was measured with a caliper under a 3 \times loupe magnification.

RESULTS

The rise in tension became obvious 30 minutes after the instillation of D.F.P. and increased during the following hour; the tension then fell, but usually remained elevated for 4 to 6 hours. The degree of ocular hypertension varied greatly in individual animals. The maximum tonometer readings generally ranged between 30 and 50 mm. Hg, but measurements from

an average protein level of 40 to 50 mg. percent which is on the high side of the range considered normal for rabbits.

The depth of the anterior chamber between the posterior surface of the cornea and the anterior pole of the lens was between 2½ and 3½ mm. depending on the size of the eye or the age of the rabbit. No clear or constant difference in depth was noted between eyes with high tension and untreated control eyes.

COMMENT

The data presented show that the connection between the increase in tension and protein concentration in the aqueous

Fig. 1 (von Sallmann and Dillon). Changes in ocular tension after instillation of 0.2-percent solution of D.F.P. into conjunctival sac of rabbits.

25 to 30 mm. and from 50 to 60 mm. Hg were also seen. The curve of Figure 1 illustrates the course of the tension changes based on 152 readings. The protein content in the aqueous was in general lower in eyes with moderate elevation of intraocular pressure and higher in eyes with greater hypertension, but the protein readings varied greatly in eyes with similar tension values. The protein concentration ranged, for example, from 200 to 1,450 mg. percent in the group having tension values of 40 to 60 mm. Hg. The aqueous of the control eyes showed

was slight, although there was a general indication that higher protein values were found more frequently in eyes with steeper and higher rises in ocular pressure. Recalling the marked edematous swelling of the ciliary processes with the development of Greeff blebs, one might conclude that the absolute height of the ocular tension was connected with filtration of water from the circulating blood into the extracellular tissue of the processes and into the chambers of the anterior part of the eye rather than with the passage of proteins.

The location of the swollen ciliary processes in rabbits between the peripheral part of the anterior surface of the lens and the posterior surface of the iris could conceivably influence the depth of the anterior chamber and the ocular tension in various ways. Although the accuracy of the measurements on frozen eyes compares unfavorably with the photographic method devised by Friedenwald and Pierce, and others,^{6a,b,c} any major difference in depth between eyes with high tension and the control eyes could not have been overlooked.

Capillary permeability in the anterior segment of eyes after local use of D.F.P. studied with the blue Azo Dye T-1824.

The vital dye T-1824 with the supposed structural formula

was first recommended by Dawson, Evans, and Whipple,⁷ for blood-volume determination. Gregersen, Gibson, and Stead,⁸ using this dye, developed the method of measuring blood and plasma volume now widely employed. T-1824 in plasma or normal saline does not diffuse through cellophane membranes,⁹ and does not pass the choroid plexus.¹⁰ Its relatively low toxicity¹⁰⁻¹³ and its slow removal from the blood, observed by all investigators in this field, made the dye suitable also for studies of general capillary permeability in shock, and for changes of permeability in circumscribed areas. Such investigations were conducted by means of moat chambers in rabbit ears;¹² the increase of capillary permeability in experimental and human malignant neoplasms was in part established by the use of T-1824.^{15, 11} Greger-

sen and Rawson¹⁶ supplied highly suggestive evidence that, after intravenous injection, the dye becomes firmly bound to the serum albumin and that it escapes from general circulation in linkage with albumin. It appears to Gregersen and Rawson that this binding "is essentially equivalent to a tagging of albumin." The reasons for this assumption will be outlined in the discussion. On this basis, it was felt in the present study with T-1824 that permeability of capillaries in the anterior segment for protein was examined rather than permeability for a colloidal dye.

TECHNIQUE

Thirty minutes after the repeated instillation of a 0.2-percent solution of D.F.P. in one eye of albino rabbits, the

dye, dissolved, prepared, and autoclaved according to usual rules, was injected in one of the lateral ear veins in a dose of 20 mg. per kilogram. The permeation of the colored substance from circulating blood into the tissue and fluids of the anterior part of the eye was observed by transscleral transillumination and biomicroscopically. For permanent recording, a great number of Kodachromes were taken of various stages of permeation of the dye in eyes treated with D.F.P. and in the control eyes. At the end of the observation period, the tension was measured, the aqueous withdrawn for protein determination, and the eyes dissected to allow direct inspection of the ciliary processes. Their staining in the treated and control eyes was also photographed in color. Finally the iris and ciliary body were removed,

fixed in acetone, embedded in paraffin, sectioned, and studied microscopically without additional staining.

In a group of three animals, the cytochrome oxydase of the ciliary epithelium was inhibited by cyanide iontophoresis in one eye with the technique previously reported.¹⁷ The D.F.P. solution was instilled in both eyes 20 minutes later. This procedure was followed after 20 minutes by intravenous injection of the dye. The changes in the caliber of the vessels and the appearance of the dye compound in the anterior portion of the eye was observed in the usual way.

Three albino rabbits serving as controls were injected in the same manner with T-1824 without preceding treatment with D.F.P. or tonometric measurements. The animals were killed after one hour by intravenous injection of a 2-percent solution of sodium pentobarbital, then the eyes were removed without exerting undue pressure and were dissected in a frontal plane about 3 mm. behind the limbus. The vitreous and lens were gently removed and the posterior surface of the ciliary body and the iris were exposed for examination with the loupe or wide-angle microscope and for color photography.

RESULTS

In control animals, no trace of dye was seen outside the vessels of the limbus and iris when examined with strong light and loupe magnification or under the 30 \times enlargement of the corneal microscope. There was a light blue coloration of some ciliary processes, which indicated slight permeability of ciliary capillaries for the dye-protein complex in untreated eyes. Staining of several ciliary processes was somewhat more marked in the eyes of a young animal weighing less than 2 kg. No dye was seen in the primary aqueous.

Similar results were observed in the

control eyes of rabbits receiving D.F.P. treatment on the contralateral eyes; that is, no dye passed through the walls of the limbus and iris vessels into the tissue. However, many ciliary processes showed a light-blue staining which did not extend into the tissue of the iris. The aqueous was apparently free of dye.

The eyes on which D.F.P. had been

Fig. 2 (von Sallmann and Dillon). Protein content in aqueous and ocular tension one hour after instillation of D.F.P. in rabbits.

used prior to the injection of the dye had dilated limbal vessels and distended iris capillaries, mostly in the pupillary part, but no permeation of the colored substance through the walls of these dilated vessels occurred. On the other hand, under transscleral transillumination, a progressively more intense staining of the ciliary processes became visible, followed within five minutes by the appearance of blue lines in the iris. They were not related to the vessels of the iris, but clearly signified the spreading of the colored material from the ciliary processes along their insertions at the posterior surface of the iris. The blue lines later lost their sharpness as the dye complex diffused into the iris tissue and escaped from its anterior surface into the aqueous. At a later stage, a dark-blue stained aqueous emerged from the posterior chamber

through the pupil into the anterior chamber. All these changes could be seen macroscopically and were well demonstrated by color films.

The inner surface of the ciliary body and of the iris showed a homogeneous deep-blue ring corresponding to the corona ciliaris. The accumulation of dye in the processes outside the vessels was so abundant that no attempt was made to examine for a gradient of vascular permeability along the arterioles, capillaries, and venules in the sense of Rous and Smith.¹⁸

The primary aqueous of the eyes which had been instilled with D.F.P. showed a light blue color about 30 minutes after the injection of the dye. The intensity of the dye could not be estimated either by the common slitlamp technique or with the addition of filters. It could only be estimated on withdrawn samples, and in these the concentration of dye and protein in the aqueous seemed roughly proportional. Spectrophotometric measurements of the optical density values in the small amount of aqueous available (0.1 cc. was used in protein measurements) were not attempted in this study.

Several phases of the diffusion of T-1824 from circulating blood into the tissue of the ciliary processes could be distinguished microscopically on unstained sections. First the interstices of the ciliary processes appeared homogeneously tinted, occasionally with a moderately more intensive staining of the vascular wall. Thirty minutes after injection, the colored material was seen in many processes in the form of blue bands underneath the covering layers of epithelium. In several instances, the dye was later visible within the epithelial layers. There was no evidence, however, that the dye had entered the cytoplasm of the cells. Two hours after the injection, a few histiocytes in the processes contained blue

granules. Later stages were not examined.

The diffusion of the dye into the structures of the ciliary processes and iris and into the aqueous occurred in the same way in eyes which had been treated with cyanide iontophoresis and D.F.P. instillations as in eyes in which D.F.P. had been used alone. The banking of the colored substance underneath the epithelial layers was also similar to that of the control eyes. As far as can be judged from fixed preparations, the inhibition of the indophenol oxydase in the ciliary epithelium apparently did not change the permeation of the dye from the blood into the tissues and chambers of the anterior part of the eye.

COMMENT

Gregersen and Rawson¹⁶ explained the slow escape of T-1824 from the blood, which greatly exceeded the disappearance rate of structurally related diazo dyes by its combining with proteins. The nature of the linkage is not known. Rawson and Moore¹⁹ showed in electrophoresis experiments that the dye was wholly bound by the albumin fraction of the serum up to a molar concentration of 10:1; that is, 1 mole albumin may combine with as many as 10 moles of T-1824. The affinity to albumin markedly surpassed that of trypan blue and niagara sky blue as concluded from the results of Rawson's celophane staining test. No dissociation of the dye-albumin compound occurred in the electrophoretic cell or in ultracentrifugation where the dye came down with the albumin.

In general the histologic examination of the ciliary processes of albino rabbits did not reveal, in the early phases, a preferential binding to constituents of the plasma membrane, the cytoplasm of cells, or other tissue elements. The appearance of protein and dye in the Greeff blebs and

the roughly proportional content of dye and protein in the aqueous strengthened the impression that a splitting of dye from protein did not occur during the permeation from the blood through the membranes of the blood-aqueous barrier, and that the dye-albumin complex passed into the aqueous as a whole. From the already mentioned binding capacity of albumin, it can be seen that the amount of dye injected fell far below this value.

In normal undisturbed rabbits' eyes, a small amount of the colored material entered from the blood into the tissue of a few processes. In view of the relatively low toxicity of the dye this would indicate that the ciliary capillaries of rabbits possess a moderate degree of protein permeability. It is known that the physiologic impermeability of the capillary wall to protein is not uniform in various areas of the peripheral circulatory system, and it has been shown with other colloidal dyes that under pathologic conditions the capillaries of the ciliary processes are more permeable than the capillaries of the iris. Such a gradient of permeability between limbus and iris and ciliary capillaries could be observed in the present study in the untreated eye, but much more convincingly by dilating the vessels of these three systems in the anterior portion of the eye by means of the anticholinesterase D.F.P. The retention of the dye complex by the wall of the limbus and iris capillaries was not changed in the state of dilation. It is interesting that Rocha e Silva and Dragstedt²⁰ and others could not produce a positive trypan blue reaction by injecting acetylcholine intradermally in an abdominal area of rabbits. Similarly, Last and Loew²¹ did not observe increased capillary permeability tested with this method in the rabbits' skin by substituting the longer acting acetyl-methylcholine for acetylcholine.

The blue color of the dye T-1824 which

proved beneficial in measurements of blood volume was also of advantage in the study on eyes of albino rabbits. Certain difficulties in the interpretation of experiments with fluorescein were eliminated by the use of T-1824, as its initial diffusion from the circulating blood into the loose tissue of the ciliary processes, its spreading into the iris, the escape from the iris surface into the aqueous, and the outpouring of dark blue aqueous from the posterior chamber through the pupil could be readily demonstrated.

The local action of D.F.P. on the vessels of the limbus.

The dilation of the vessels in the anterior part of the eye and the pronounced increase in permeability of the ciliary vessels to protein was supposedly elicited in the present experiments by the intensified action of the undestroyed cholinergic chemical mediator. It was not clear how this effect was brought about or where the point of attack lay. To our knowledge, no work on the pharmacology of D.F.P. has been reported in regard to its local action on vessels. On the other hand, the innervation of finer branches and the intimate anatomy of the functional unit of the capillary bed—capillary-metarteriole-venule—in the anterior portion of the eye, has not been studied sufficiently. Observations of the limbus vessels under a 30-fold magnification of the corneal microscope supplied several suggestive data on the local action of D.F.P.

TECHNIQUE

In an area of the limbus of one eye of albino or chinchilla rabbits which could be well exposed under the corneal microscope, the distribution and relative calibration of small arterioles, capillaries, and veins were outlined in a sketch. Then a 0.2-percent solution of D.F.P. was instilled into the conjunctival sac and the

sequence of caliber changes of various parts of the vascular net was registered. After 15 minutes, the minimal effective dose of epinephrine for closure of capillaries was determined on the eye which had received the D.F.P. drops as well as on the contralateral control eye. The caliber changes of the vessels in the selected area of the limbus were again outlined and compared to those observed after the use of D.F.P. Photographic records could not be obtained.

RESULTS

The dilation of the limbus vessels was noted within 10 minutes after several drops of the D.F.P. solution had been employed. The diameter of arterioles, metarterioles, and capillaries increased about the same time. No premature distention of capillaries preceding the hyperemia of arterioles was seen. Under the conditions of the experiments, it could not be decided whether the region of the precapillary sphincter itself responded synchronously with the arterioles.

The concentration of the minimal dose of epinephrine hydrochloride necessary for marked constriction of the vascular tree and closure of some capillaries was 1:500,000 to 1:1,000,000, when several drops of this solution had been deposited in the conjunctival sac. This dose had to be increased 20 to 100 times, that is to about 1:10,000 for a comparable constriction of the terminal branches of the limbus vessels of eyes under the influence of D.F.P. The narrowing of the capillaries took place simultaneously with the great reduction in the size of the diameters of the arterioles and metarterioles.

COMMENT

In general, the technique of Chambers and Zweifach²³ and Zweifach²² devised for the mesentery capillaries of rats was

applied in the epinephrine experiments. The magnification which these authors could utilize for their examination of the vessels in the meso-appendix was at least three times greater and the conditions for accurate observations were by far more favorable than those in the experiments on the limbus vessels of rabbits. Here it was impossible to identify structural details such as the location of Tannenberg's²⁴ "Pfoertner Zellen" or the precapillary sphincter, and to judge the sensitivity of this area to effective threshold concentrations of epinephrine in comparison with the sensitivity of arterioles or metarterioles.

Capillaries and arterioles changed in caliber at about the same time both in dilation after use of D.F.P. and in constriction induced by subsequent instillation of epinephrine hydrochloride (1:10,000). These results suggest that accumulated acetylcholine acted on the neuromuscular junction of the arterioles and that the induced dilation of these branches with its augmented blood flow led immediately to a passive filling of the capillaries. This concept is in line with the widely accepted opinion^{22, 25, 26} that the filling of mammalian capillaries and venules follows passively the dilation and contraction of the supplying arterioles.

The influence of drugs on the increased capillary permeability induced by the use of D.F.P.

The signs of increased capillary permeability including elevation of intraocular pressure in the test lesion could be variously influenced by drugs. In these experiments changes in tension, in protein content of the aqueous, in diffusion of the dye T-1824, and in size of the pupil were observed and correlated. Four groups of pharmaceuticals were examined: (1) adrenergic compounds, (2) pituitrin (3)

a calcium salt and adrenal cortex extract, and (4) histamine antagonists. The measurements of protein content in the aqueous and the use of the dye followed the technique previously described. Variations in timing of the experiments and in application of the drug will be dealt with separately in the individual sections.

1. ADRENERGIC DRUGS

TECHNIQUE

Epinephrine and neosynephrin were tested. Epinephrine hydrochloride, 0.1 cc. of a solution (1:1,000), was injected subconjunctivally underneath the superior rectus muscle of the right eye 20 minutes

RESULTS

The subconjunctival injection of epinephrine hydrochloride on the right eye prior to treatment of both eyes with D.F.P. prevented the rise in tension of this eye. The differences of the tension values between the two eyes were consistently greater 30 minutes after the last instillation of D.F.P. drops. At this time the averages of 10 experiments were 18.3 mm. Hg, right eye, and 43.5 mm. Hg, left eye. Ninety minutes after the use of D.F.P. the respective values of seven experiments read: 16.7 and 25.9 mm. Hg, and in the three eyes which were measured 150 minutes after employment of

Fig. 3 (von Sallmann and Dillon). Changes in ocular tension and protein levels in the aqueous after instillation of D.F.P. preceded by subconjunctival injection of epinephrine hydrochloride (0.1 cc. 1:1,000 dilution) in one eye.

prior to repeated instillations of the solution of D.F.P. in both eyes. One drop of the emulsion of neosynephrin hydrochloride, 10 percent, was deposited three times in the right eye 30 minutes before or 10 minutes after the use of the D.F.P. solution in both eyes. In the experiments in which the use of neosynephrin preceded that of D.F.P., three drops of the blank vehicle were applied in the left eye. The measurements of the pupillary diameters were made with a pencil flashlight at a distance of one foot.

D.F.P., 22 and 29.3 mm. Hg. The protein readings in the aqueous of six rabbits at the 90-minute interval showed averages of 354.4 mg. percent, right eye, and of 643.7 mg. percent, left eye. In the albino rabbits, which had received the dye T-1824 intravenously with the usual technique, the right iris remained unstained. After dissection of the eyes, the right ciliary processes were considerably less blue than in the control eyes and were often unstained in the upper medial sector corresponding to the area of in-

jection. Thirty minutes after the use of D.F.P., the diameter of the right pupil measured from 3.5 to 5 mm. while the average diameter was 1 to 2 mm. in the control eyes.

Neosynephrin-hydrochloride emulsion applied to the right eye before the use

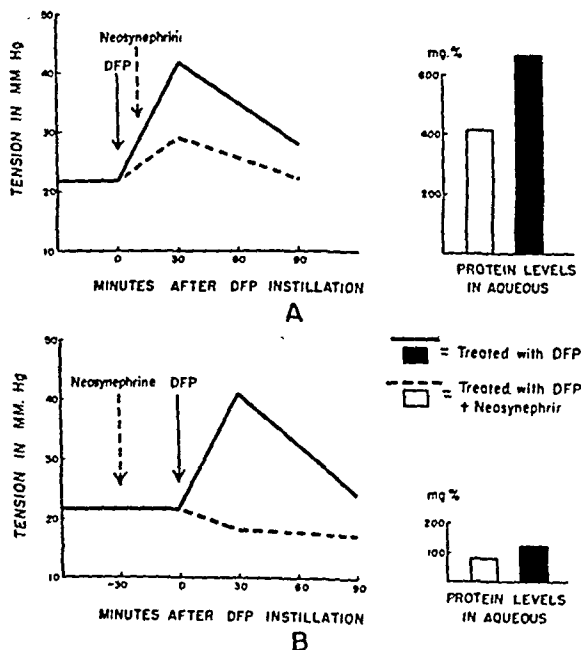

Fig. 4 (von Sallmann and Dillon). Changes in ocular tension and protein levels in the aqueous after the instillation of D.F.P. (A) followed by instillation of neosynephrin-hydrochloride emulsion (10 percent); (B) preceded by neosynephrin-hydrochloride emulsion (10 percent).

of D.F.P. counteracted the effect of D.F.P. on the intraocular pressure. The tension values after 30 minutes were: R.E., 17.5 mm. Hg, and L.E., 42.3 mm.; and after 90 minutes: R.E., 17 mm. Hg, and L.E., 24 mm. (average of four experiments).

The protein in the aqueous measured less than 80 mg. percent in the right eye and 111 mg. percent in the left. The aqueous of the eyes treated with neosynephrin was not colored and the ciliary processes were stained only light blue. The size of the pupil differed less from

the size in the control eyes (3 to 4 mm.: 1 to 2 mm.) than in the epinephrine experiments.

The instillation of neosynephrin 10 minutes after the use of D.F.P. influenced the tension to the following extent—after 30 minutes: R.E., 29.3 mm. Hg; L.E., 41.8 mm.; after 90 minutes: R.E., 22.5 mm. Hg; L.E., 27.5 mm. (average of four experiments). The protein measurements in the aqueous gave an average of 337 mg. percent in the right eye and 532 mg. percent in the left. This series did not contain tests with T-1824. The relation of the pupillary diameters of both eyes was comparable to that in the preceding experimental group.

COMMENT

It is obvious that the two adrenergic compounds eliminated the elevation in tension, occurring in rabbits after the use of D.F.P., when they were administered prior to or after the instillation of D.F.P.

The curve of rising tension in the control eye did not deviate from the average standard curve (fig. 1) at the 30 minute interval, but declined rapidly thereafter, so that values below 30 mm. Hg were reached after 90 minutes. This early decline of the tension curve suggested absorption of the sympathomimetic compound from the conjunctival sac of the treated right eye into the general circulation, affecting the other eye. The comparatively small difference between the protein reading in the aqueous of both eyes (especially in the experiments with neosynephrin—first group) can also be interpreted in the same way. The results of the dye experiments did not contribute to answering this question since quantitative measurements of the optical density in the aqueous were not carried out.

The use of epinephrine or neosynephrin greatly interfered with the con-

striction of the pupil due to D.F.P. The dilation of the pupil in this combined treatment must be considered a hazard already experienced in a few instances of human chronic glaucoma with high tension, which did not respond favorably to local medication with D.F.P. The addition of epinephrine base, dissolved in oil, led to a further widening of the pupil and subsequent rise in tension.

Thirty minutes later the tension was recorded, and the D.F.P. solution was instilled in one eye in the experiments with systemic injection or in both eyes of rabbits which had received the topical treatment unilaterally.

RESULTS

Intramuscular injection of pituitrin caused a drop in tension of untreated

Fig. 5 (von Sallmann and Dillon). Changes in ocular tension and protein levels in the aqueous after the instillation of D.F.P. preceded by instillation, subconjunctival or intramuscular injection of pituitrin.

2. PITUITRIN

The effect of posterior pituitary preparations was studied with the Parke Davis product, which contains 20 international units per cc. The drug was administered by the systemic route or topically on untreated eyes and on eyes under the influence of D.F.P.

TECHNIQUE

The tension was taken prior to any medication. The pituitrin preparation was injected intramuscularly in a dose of 5 units/kg. or under the conjunctiva in one eye in a dose of 2 units. In a few instances the solution was instilled into the conjunctival sac instead of being injected.

eyes from 19.3 mm. Hg to 10.5 mm. after one hour and to 15.5 mm. after 150 minutes (averages of six experiments). It overcompensated the effect of D.F.P. for one hour with average readings of 14 mm. Hg, rising to 24 mm. after two hours.

The initial tension of 21.8 (six experiments) decreased to 16.3 mm. Hg, 30 minutes after the subconjunctival injection of 2 units; the tension of the other eye was not changed at this time. In 18 eyes with an average initial tension of 19.5 mm. Hg, the heightening of tension after use of D.F.P. was eliminated for 90 minutes (average readings after 30 minutes 18.3 mm. Hg and after 90 minutes 20.8 mm.). In these experiments

with the topical use of pituitrin the measurements of the protein content in the aqueous revealed a ratio of 66.7 to 283.3 mg. percent (average of four experiments) for the eyes treated with pituitrin and D.F.P. and the eyes treated with D.F.P. respectively. The instillation of the pituitrin gave results like those obtained with the local injection.

In the dye experiments the difference in the intensity of staining of aqueous, iris, and the ciliary processes between the two groups of eyes was very marked; that is, the aqueous was unstained, the iris showed no escape of the dye, and the ciliary processes were tinted much less than those of the control eyes, especially in the upper medial sector. When the anterior chamber of both eyes was emptied 150 minutes after the injection of pituitrin in the right eye, the secondary aqueous was almost unstained in contrast to the very dark-blue colored aqueous which filled the anterior chamber of the left eye.

The subconjunctival injection of pituitrin prevented the maximal constriction of the pupil observed after use of D.F.P., but the difference between the two eyes was markedly less (2-3 mm.: 1.5-2 mm.) than in the experiments with epinephrine or neosynephrin.

COMMENT

The systemic and local uses of pituitrin were beneficial in blocking the action of D.F.P. on the tension of rabbits' eyes. The protein readings in the aqueous and the observations with the dye indicated that the prevention of ocular hypertension was connected with the vasoconstricting effect of the hormone which lasted several hours as shown best in the formation of an almost colorless secondary aqueous 150 minutes after the local use of pituitrin. The comparison of the protein concentrations in the aqueous and of the changes in ocular pressure of the

eyes treated with pituitrin and D.F.P. with those treated with D.F.P. alone pointed again to systemic absorption of the hormone from the depot beneath the conjunctiva. This assumption explained the difference of values in control eyes of this series from averages obtained in rabbits on which only D.F.P. was used. It might be of practical importance that the topical use of pituitrin secured the full effect on the permeability of the ciliary capillaries with only moderate inhibition of the D.F.P. miosis.

3. CALCIUM. ADRENAL CORTICAL EXTRACT

It has been stated that any procedure which alters the physicochemical properties of the intercellular cement affects the rate of filtration across the capillary wall. Chambers and Zweifach²³ demonstrated with an elaborate technique that calcium-free perfusion fluid at a slightly acid pH rendered the capillary wall leaky by softening and washing away the intercellular cement, and that doubling the normal amount of calcium in the fluid caused overproduction of the cement material. This experimental evidence concerning the importance of the calcium concentration in the perfusate for the filtration across the capillary wall was the basis for investigations on the effect of a calcium salt variously introduced in eyes in which protein permeability of the ciliary capillaries had been increased by instilling D.F.P. solution in the conjunctival sac.

The use of adrenal cortical extract was considered in view of the studies of Swingle, Parkins, and Remington,²⁷ Menkin,²⁸ Freed and Lindner,²⁹ and others, in which the integrity of the peripheral vascular system and the maintenance of normal capillary permeability was shown to be controlled in some way by the adrenal cortex. There is no experimental evidence that the extract influences capillary permeability by changing physical condi-

tions of the intercellular cement, but the possibility of such a mechanism cannot be ruled out.

TECHNIQUE

A. Calcium. Calcium gluconate, 10 percent (pH 5.5),* was either injected under the conjunctiva (0.2 cc.), introduced by anode corneal iontophoresis (1.5 ma. for 5 minutes), or given intravenously (5 cc. per kg.). D.F.P. instillations on both eyes followed the local procedures after 30 minutes and preceded the systemic introduction by 10 minutes.

RESULTS

The subconjunctival use of calcium salt on the right eye caused severe chemosis and did not noticeably alter the rise in tension after use of D.F.P. (average of four experiments: R.E., 56 mm. Hg; L.E., 60 mm.). When calcium iontophoresis was employed on the right eye 30 minutes before depositing D.F.P. drops in both eyes, tension curves of both eyes reached almost the same levels one hour after the D.F.P. medication (average of six experiments: R.E., 34 mm. Hg; L.E., 39 mm.). Four experiments with the intravenous injection of calcium gluconate, followed after 10 minutes by the use of D.F.P., showed rise in tension to an average of 50 mm. Hg (four experiments). In the iontophoretically treated eyes the protein level in the aqueous slightly exceeded (average of 613 mg. percent) that of the control eyes (average of 536.3). The diffusion of the dye T-1824 and the constriction of the pupil caused by the use of D.F.P. were not essentially changed under the treatment with the calcium salt.

B. Adrenal-cortex extract. The study was limited to the use of one preparation

of whole cortical extract (Upjohn), which contained 50 dog units or 2.5-rat units per cc. The intravenous route was selected in two series. After measuring the tension of both eyes, 0.5 cc. per kg. of extract (25 dog units) was injected and the changes in intraocular pressure were followed over a period of 24 hours without any other treatment. In another group of animals the protein concentrations in the aqueous were determined 90 and 120 minutes after the experiment was begun and were compared with those of untreated rabbits which had been subjected to similarly timed tonometry. In a second series three drops of the D.F.P. solution were placed in one or both eyes 15 minutes after injection of the extract. Tonometric readings were obtained 30 minutes to 24 hours after instillation of the D.F.P. solution. T-1824 was used only in a few instances.

A small group of rabbits was treated by injection of 0.05 cc. of extract under the conjunctiva; 30 minutes later the D.F.P. solution was applied and the tension was determined after 30, 90, 150 minutes, and 5 hours.

RESULTS

The intravenous use of adrenal cortex extract in otherwise untreated animals was followed by a gradual lowering of the ocular pressure to a minimum reached six hours after injection. The average difference between the readings taken before the injection and the values six hours later was 7 mm. Hg (nine experiments). Massage effect of the tonometric procedure was improbable since in control experiments such a response was absent when tonometric measurements had been repeated at hourly intervals. The tonometry on untreated rabbits' eyes apparently caused some irritation which led in several instances to an increase of protein content in the aqueous; in one instance

* Neo-calglucon, Sandoz Chemical Works, Inc., was used.

it reached 196 mg. percent. This effect was not evident in eyes of rabbits which had received the injection of adrenal-cortex extract. Here the average of the protein content of 10 eyes was 42.7 mg. percent.

The rise in tension due to the use of D.F.P. was not greatly influenced by treatment with adrenal-cortex extract.

COMMENT

Calcium gluconate introduced by iontophoresis, subconjunctival injection, or by the intravenous route was ineffective in counteracting the increase in capillary permeability and in ocular tension following the local use of D.F.P. in rabbits. The permeation of ionized calcium into the anterior chamber after topical sur-

Fig. 6 (von Sallmann and Dillon). Changes in ocular tension after instillation of D.F.P. preceded by intravenous injection of adrenal-cortex extract (Upjohn).

The tension rose from a base value of 23.8 mm. Hg to maximal values around 32.4 mm. Hg in the first 90 minutes and fell to 26.5 mm. Hg after five hours (five rabbits). The control eyes of these rabbits not treated with D.F.P., exhibited a decrease in tension of about 5 mm. Hg. In a simultaneously observed control group of rabbits (four eyes) which were only under the influence of topical D.F.P. applications, the tension increased to an average of 36 mm. Hg. Subconjunctival injection of the hormone preparation in one eye, succeeded by the use of D.F.P. on both eyes 30 minutes later, failed to prevent increase of ocular pressure in two instances and was questionably beneficial in two other instances.

face application so far has not been determined. It will be necessary to augment the number of observations and to modify the experimental procedure before any broader evaluation of the effect of calcium on the ciliary capillaries is permissible.

It is not known how the adrenal cortical extract acts on capillary permeability, and direct observations on the influence of adrenal steroids on capillaries are sparse. Menkin,²⁸ and Freed and Lindner²⁹ noticed reduced filtration of trypan blue from the circulating blood into areas of skin injected with leukotaxin after cortical substances had been added to the toxin. Fine and Fischmann,³⁰ using desoxycorticosterone acetate, confirmed the decrease in the rate at which various dyes

leave the capillaries of the rabbit's ear under the influence of the synthetic product but thought that this effect on the diffusion of the dye was not related to an alteration in capillary permeability. Hyman and Chambers³¹ observed that whole cortical extract added to the perfusion fluid in a dilution of 10^{-8} reduced the rate of edema formation in the frog's hind limbs; the authors were unable to conclude, however, whether this effect was due to a change in capillary permeability. If their results are taken to indi-

4. HISTAMINE ANTAGONISTS

Local mechanical stimulation, lack of oxygen, or any kind of injury may cause considerable transudation of fluid from the blood into the tissue due to increase in capillary permeability. It has been thought that under such conditions the liberation of histamine or a special H substance may give rise to capillary dilation and sometimes to increased permeability. Although the validity of this theory was questioned (Menkin³⁴), the possibility of activating an histamine mecha-

Fig. 7 (von Sallmann and Dillon). Changes in ocular tension after instillation of D.F.P. preceded by instillation of benadryl-hydrochloride solution (2 percent).

cate such a change, an influence of the hormone on the tonus of the capillary endothelium (Chambers³²) or on adsorption of proteins at the intercellular cement (Zweifach³³) could offer an explanation for the phenomenon. At this stage of the investigation no conclusion can be drawn concerning the mechanism by which the cortical extract, injected intravenously, lowered the ocular tension in undisturbed rabbit eyes and prevented the rise of protein content of the aqueous in eyes irritated by repeated tonometry. Further studies are warranted.

nism by stimuli, such as stretching of tissue or rapid increase of the tissue pressure, cannot be excluded. From this viewpoint, the experiments on the effects of drugs on the test lesion under consideration were extended to several histamine antagonists. Three representatives of this group were selected: benadryl (β dimethylaminoethyl benzhydryl ether), hydrochloride, pyribenzamine (N' -benzyl- N' -dimethylaminoethyl aminopyridine) hydrochloride, and antistine (2 [N-phenyl- N' -benzyl-aminomethyl] imidazolin) sulphate.

TECHNIQUE

The compounds were applied topically only by instillation since subconjunctival injections caused considerable irritation. Two drops of a 2-percent solution were deposited in the conjunctival sac, three times, at 3-minute intervals in all experiments. Fifteen minutes later the solution of D.F.P. was used on both eyes. In con-

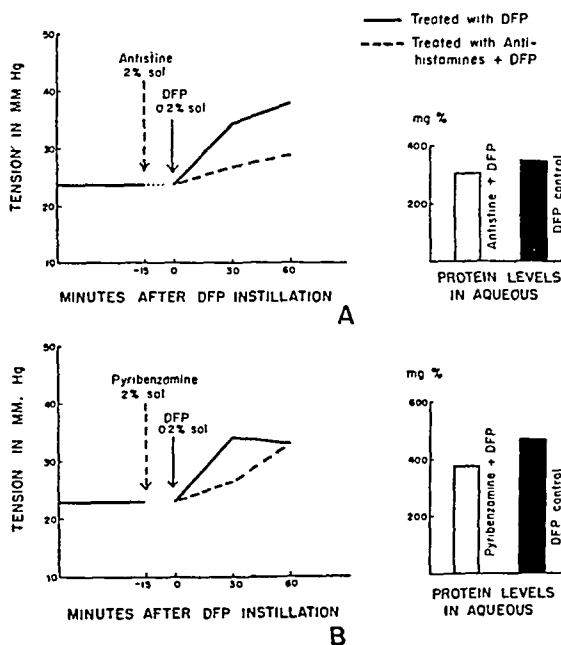

Fig. 8 (von Sallmann and Dillon). Changes in ocular tension and protein levels in the aqueous after instillation of D.F.P. preceded (A) by instillation of antistine-sulphate solution (2 percent); (B) by pyribenzamine-hydrochloride solution (2 percent).

formity with the procedure in the case of other drugs, the tension was taken before treatment was initiated and 15 minutes later; that is, immediately before the employment of the D.F.P. solution. The changes in tension were then followed over a period of 90 minutes and the protein content was determined at the end of this period. In connection with these studies pooled aqueous of eyes pretreated with D.F.P. was tested pharmacologically for histamine activity on the isolated gut of the guinea pig.*

RESULTS

A. Benadryl hydrochloride. One hour after the instillations of the solution of D.F.P., the tension average on the right eyes treated with benadryl and D.F.P. was 24 mm. Hg, on the left eyes treated with D.F.P. alone, 38 mm. Hg (averages of four experiments). The protein concentrations in the aqueous of the right eyes were scattered from 60 to 305 mg. percent and on the left eyes from 60 to 411.4 mg. percent. The difference in the averages (right eye 150, and left eye, 200) cannot be considered significant. The diffusion of T-1824 was delayed in both eyes and moderately more marked in the eyes which had not received benadryl. The pupils of these eyes were relatively dilated when compared with the control eyes (3.4 to 1.2 mm.).

B. Pyribenzamine hydrochloride. The use of this compound did not prevent the tension rise from a base value of 22.8 mm. Hg to 33.7 mm. after one hour (three experiments); the control eyes showed at this time a similar elevation of 36 mm. Hg. The average protein level in the aqueous of the treated eyes was 376 mg. percent when the histamine antagonist was used and 470 mg. percent in the control eyes. Corresponding to these readings, the permeation of the dye was less pronounced in the eyes treated with pyribenzamine. The pupils of these eyes contracted less than in eyes on which D.F.P. had been used alone (3 to 4 mm. right to 1 to 2 mm. left).

C. Antistine sulphate. The tension of eyes treated with antistine and D.F.P. showed an average increase from 23 to 29 mm. Hg one hour after instillation of D.F.P. solution. Control eyes on which D.F.P. alone had been used gave an av-

* These experiments were conducted by Dr. A. Gellhorn of the Department of Pharmacology, College of Physicians and Surgeons, Columbia University.

erage reading of 38 mm. Hg (four experiments). The group of eyes under direct influence of both substances contained 301.8 mg. percent protein, the control eyes 352.5 percent. The intensity of the blue staining also differed from rabbit to rabbit. Usually the diffusion occurred earlier and was greater in the eyes treated with D.F.P. only. In contrast to the two other drugs of this group, antistine did not interfere with the development of the D.F.P. miosis.

When the aqueous of both eyes of five rabbits was withdrawn and pooled 2, 4, and 18 hours following the treatment with D.F.P. (three experiments on 15 rabbits) and amounts of aqueous (up to 1 cc.) were added to a gut preparation in 10 cc. of oxygenated Tyrode solution, no contraction of the gut was observed. A 0.5-cc. solution containing 1.0 γ per cc. of histamine diphosphate and 0.5 cc. of an 0.000005 molar solution of acetylcholine caused intensive contraction of this preparation. It was concluded that these substances, when present in the aqueous, did not reach the effective threshold level.

COMMENT

The new antihistamine drugs possess, besides their main action and anesthetic properties, a parasympatholytic side action and the ability to potentiate adrenergic responses.³⁵⁻³⁹ The quantitative relation between these individual actions varies with the different compounds. Although the ineffectiveness of pooled aqueous of eyes pretreated with D.F.P. on the guinea-pig gut does not exclude the presence of a histamine mechanism, it appears at the present time more plausible to assume that the positive responses observed on tension and in a moderate degree on permeability of ciliary capillaries were brought about by one or another of the side actions of the drugs. The dilation of the pupils of normal rabbits would in-

dicate the action of a sympathomimetic stimulus; however, antistine did not prevent full development of D.F.P. miosis but did influence the tension satisfactorily. The literature on antistine,⁴⁰⁻⁴² a drug which had been used effectively in allergic types of conjunctivitis,⁴³ does not give information on its anticholinergic activity.

The experiments with antihistaminic drugs (like those with calcium and adrenal cortex extract) should be considered preliminary. Benadryl and antistine could have exerted the beneficial influence on the ocular tension of the test lesion by mechanisms other than those operative on capillary permeability. The small difference in the protein level and permeation of the dye T-1824 between eyes treated with histamine antagonists and D.F.P. and eyes on which D.F.P. had been used alone might be explained by absorption of the former compounds from the conjunctiva of the treated eye in amounts sufficient to affect protein permeability of the ciliary capillaries in the other eye. The reduction of the protein level in the aqueous and of the staining intensity in ciliary processes of eyes treated with benadryl and antistine was relatively moderate. This differs greatly from the results of experiments with adrenergic drugs and with pituitrin. Further studies on this new group of drugs on the eye will be necessary for a better understanding of the observed action.

SUMMARY

1. The rise in ocular tension following instillation of a 0.2-percent solution of di-isopropyl fluorophosphate in rabbits is apparently caused by increased permeability of the ciliary capillaries.

2. The outpouring of serum proteins into aqueous roughly paralleled the elevation of tension, but there were great discrepancies in individual experiments be-

tween height of tension and concentration of protein.

3. The blue Azo dye T-1824 was found useful in grading the capillaries of the limbus, iris, and ciliary processes for permeability to the dye and probably to serum albumin. The permeability of the ciliary capillaries greatly exceeded that of the capillaries of the limbus and iris under the influence of the same stimulus.

4. The diffusion of the dye from the circulating blood into the tissue interstices of the ciliary processes and the permeation into the iris and into the chambers of the anterior part of the eye were studied under the corneal microscope and histologically in sections of ciliary body and iris.

5. Biomicroscopical observations on the limbus vessels suggested that the capillaries dilated passively and simultaneously with the distention of the supplying arterioles and metarterioles caused by the cholinergic chemical mediator.

6. Adrenergic drugs and pituitrin effectively counteracted the action of D.F.P. on the ocular tension and capil-

lary permeability in rabbits. The former diminished the miotic effect of D.F.P. far more than did pituitrin.

7. With the technique used, calcium gluconate and adrenal-cortex extract failed to influence the signs of increased permeability of the ciliary capillaries induced by D.F.P.

8. Benadryl, antistine, and to a minor degree pyribenzamine, prevented or reduced the elevation of intraocular pressure caused by D.F.P., but the action on capillary permeability was moderate. Only antistine did not weaken the miotic action of D.F.P.

We are indebted to Dr. M. I. Gregersen for supplying us with the dye T-1824, to Dr. B. W. Zweifach for valuable suggestions, and to Dr. A. Gellhorn for conducting the pharmacological tests with aqueous on the isolated guinea-pig gut.

We want to express our thanks to the the Research Division of Ciba Pharmaceutical Products, Inc., for the donation of the drugs pyribenzamine hydrochloride and antistine sulphate.

TRANSFER OF ASCORBIC ACID AND RELATED COMPOUNDS ACROSS THE BLOOD-AQUEOUS BARRIER*

V. EVERETT KINSEY, PH.D.
Boston, Massachusetts

The high concentration of ascorbic acid in the aqueous humor compared with that in the blood has been offered as presumptive evidence that this compound enters the aqueous humor as a result of a secretory process. Previous studies have shown that while this is true for adult animals the concentration of ascorbic acid in the aqueous humor in young animals is essentially the same as in the blood.¹ The difference in young animals has been explained by assuming that the blood-aqueous barrier is sufficiently permeable to permit rapid diffusion from the aqueous back into the blood.²

The implications inherent in the belief that the total transfer of ascorbic acid across the blood-aqueous barrier occurs as a result of a secretory process in adult animals, on the one hand, whereas, a predominant portion of the transfer occurs as a result of diffusion in young animals, on the other hand, have not been con-

sidered previously. Thus, if the transfer took place by secretion, it would be expected that the amount of ascorbic acid which could be transferred across the blood-aqueous barrier would be limited by some factor other than the quantity present in the blood; that is, that the secretory process is capable under ordinary conditions of handling but so much ascorbic acid. If the transfer occurs as a result of diffusion, it would be expected that there would be a direct relationship between the concentration in the aqueous and the blood irrespective of the concentration in the latter fluid. One of the objects of the present paper was to subject these inferences to experimental verification.

A second objective concerns the question of the specificity of the secretory process for compounds structurally like ascorbic acid. It is well known that other carbohydrates having similar size and solubility (namely, glucose) without exception are normally found to be present even in adult animals in the aqueous in lower concentration than in the blood. This is suggestive that any secretory process which can transfer ascorbic acid

*From the Howe Laboratory of Ophthalmology, Harvard Medical School. This work was supported in part by a grant from the John and Mary R. Markle Foundation. Read at the 16th scientific meeting of the American Association for Research in Ophthalmology, Inc., Atlantic City, June 10, 1947.

across the blood-aqueous barrier is relatively specific for this compound.

The question of the specificity of the transfer of ascorbic acid across the blood-aqueous barrier is of theoretical importance to a more complete understanding of the secretory process in general. Friedenwald and co-workers³ have shown that ascorbic acid, presumably by reason of its ability to become reversibly oxidized and reduced, acts as a mediator in the oxidation-reduction system associated with the secretory process in general. It is not known, however, whether any portion of the molecule other than that concerned with oxidation reduction, that is, the enediol, is necessary either for secretion of other components of the aqueous humor or for the secretion of ascorbic acid itself. It would appear that this question could be resolved by studying the rate of transfer across the blood-aqueous barrier of the enantiomorph of ascorbic acid, d-isoascorbic acid, and d-glucoascorbic acid. D-isoascorbic acid differs structurally only in configuration and d-glucoascorbic acid in the addition of an extra CHOH group between carbon atoms 5 and 6 of ascorbic acid. Both compounds incidentally appear to have oxidation-reduction properties identical with ascorbic acid.

MATERIALS AND METHODS

Albino rabbits were used for all of the experiments. The adult animals were fed a stock diet of Purina rabbit pellets, and the young animals were housed with their mothers.

The test substances were dissolved in glass-distilled water and injected intraperitoneally. Samples were taken from the eye at predetermined times under topical anesthesia (tetracaine HCl) using micropipettes as described previously,¹ and blood was removed by heart puncture. Upon collection, the samples were im-

mediately placed in 4-percent metaphosphoric acid.

All of the analyses were done by means of the dichlorophenol-indophenol titration, and the results of all three compounds tested are reported in terms of ascorbic-acid equivalents. Since the method did not differentiate between the ascorbic acid normally present in the aqueous humor or blood and the compounds injected, the results must be interpreted in terms of change in concentration from the normal level. For the aqueous humor, the normal level is about 20 to 25 mg. percent; and for the blood, about 0.5 to 2.0 mg. percent.

RESULTS

As to the manner in which ascorbic acid is transferred, Figure 1 shows that the

Fig. 1 (Kinsey). Shows the change in concentration of ascorbic acid in the serum and aqueous humor at various intervals following intraperitoneal injection.

concentration of ascorbic acid reaches a maximum in the blood within 20 minutes and that the concentration in the aqueous humor also increases to reach a maximum 60 minutes following intraperitoneal injection. Since the elevated level of ascorbic acid in the aqueous humor is maintained as long as the blood level remains constant, it may be assumed that a steady state is reached at this time.

Figure 2 shows the concentration of ascorbic acid in the aqueous 60 minutes after the injection of various quantities of this compound plotted as a function of the concentration in the blood. It is evident from the graph that the concentration in the aqueous increases rapidly with

Fig. 2 (Kinsey). Shows the relative concentration of ascorbic acid in the aqueous humor and in the serum of adult rabbits.

increasing concentration in the serum until the level in the aqueous becomes 50 mg. percent. This occurs when the concentration in the serum is 3 mg. percent. With higher blood levels, no further increase in the quantity of ascorbic acid in the aqueous humor was observed, even though the concentration in the serum was elevated to 130 mg. percent.

The same experiments were repeated using young rabbits and the results are represented by the open circles in Figure 3. In this instance it will be seen that the concentration in the aqueous humor rises with increased concentration in the blood throughout the entire range. These results appear to be consistent with the hypothesis previously set forth; namely, that in adult animals ascorbic acid is transferred by secretory process, that some factor other than availability of this compound in the blood limits the amount which can be transferred across the blood-aqueous

barrier, and that in young animals the transfer takes place primarily by the process of diffusion. That the blood-aqueous barrier in adult animals is impermeable to the simple diffusion of ascorbic acid is borne out by the observation that the concentration of ascorbic acid in the aqueous humor does not increase beyond 50 mg. percent, even though the blood level is more than double this concentration. It is interesting to note that molecules considerably larger than ascorbic acid—for example, sucrose—apparently can diffuse through the blood-aqueous barrier. The distinguishing characteristic between ascorbic acid and molecules like glucose and sucrose seems to be that, at the hydrogen-ion concentration found in the aqueous, ascorbic acid is charged; whereas, the sugars are not. This finding offers further support to the theory set forth by the author elsewhere⁴ that electrolytes in general enter the eye by secretion; whereas, nonelectrolytes enter by diffusion.

With regard to the problem of the specificity of the secretory process, Figures 4 and 5 show the results of analyses made on serum and aqueous humor at various times after injecting d-iso ascorbic and

Fig. 3 (Kinsey). Shows the relative concentration of ascorbic acid (open circles) and d-glucoscorbic acid (filled circles) in the aqueous humor and serum of young rabbits.

d-gluco ascorbic acid into adult rabbits. In both instances the concentration of material titratable with 2:6 dichlorophenol indophenol (expressed as mg. percent ascorbic-acid equivalent) increased in the serum, but only in the case of d-iso ascorbic acid did the concentration of the injected material rise in the aqueous humor.

The filled circles of Figure 3 show the

Fig. 4 (Kinsey). Shows the change in concentration of d-iso ascorbic acid in the serum and aqueous humor at various intervals following intraperitoneal injection.

concentration of d-gluco ascorbic acid in the serum and aqueous humor of young rabbits. Unlike the results obtained in the adult animals, it will be seen that d-gluco-ascorbic acid enters the aqueous humor of young animals and does so in proportion to the concentration in the serum.

The results indicate that the secretory process is apparently selective for ascorbic acid or its optical isomere and are suggestive that ascorbic acid forms an integral part of the secretory mechanism as proposed by Friedenwald.³ The secretory process is not as specifically dependent upon a particular structure, however, as are the mechanisms whose malfunction results in scurvy, since d-isoascorbic and d-glucoascorbic have but 1/10 and 1/100 antiscorbutic power of ascorbic acid, respectively.

From the point of view of chemical mechanism, it may be inferred that in addition to the possible participation of that portion of the molecule responsible for the oxidation-reduction property; that is, the enol groups, the part of the molecule around carbon-atoms 5 and 6 are also necessary to the secretory process.

SUMMARY

The distribution of ascorbic acid in the aqueous humor and blood of adult and young rabbits was determined under steady-state conditions. In adult animals the concentration of ascorbic acid in the aqueous was found to increase rapidly with increasing concentration in the blood until the concentration in the aqueous reached 50 mg. percent. This occurred with a serum concentration of approximately 3 mg. percent. With higher blood levels no further increase occurred in the concentration of ascorbic acid in the aqueous even though the concentration in the blood was more than double that in the aqueous humor.

In young animals the concentration of ascorbic acid in the aqueous was found to vary directly with the concentration in the blood. These differences in distribution

Fig. 5 (Kinsey). Shows the change in concentration of d-gluco ascorbic acid in the serum and aqueous humor at various intervals following intraperitoneal injection.

were thought to indicate that ascorbic acid enters the aqueous humor as a result of a secretory process in adult rabbits; whereas, in young animals the predominating factor in determining the distribution ratio is diffusion. Furthermore, they show that in adult animals some factor, other than availability of this compound in the blood, limits the amount which can be secreted across the blood-aqueous barrier.

The specificity of the secretory process for compounds structurally like ascorbic acid was investigated by injecting d-iso and d-glucoscorbic acid into the per-

itoneal cavity and determining the rate of entrance of these compounds into the aqueous humor in adult and young rabbits. It was found that d-iso ascorbic acid entered the aqueous but no transfer of d-glucoscorbic took place across the blood-aqueous barrier in adult animals. These results indicate that the secretory process is apparently selective for ascorbic acid or its optical isomere (d-isoascorbic acid). The selectivity appears to be unrelated to the antiscorbutic action of these compounds. No selective transfer was observed for these compounds in eyes of young animals.

A STATISTICAL STUDY OF GLAUCOMA*

J. C. HOLST, M.D.

Oslo, Norway

In the introductory surveys of glaucoma in monographs and textbooks, there are many statistical data which are, to a certain extent, copied from one work to another. However, it is not always easy to gain a clear impression of the conditions mentioned; such as, the frequency of glaucoma, its distribution according to sex, errors of refraction, and so forth. For many of the conclusions quoted belie each other, often to the confusion of the reader. This may be so not only because the figures are often comparatively small, but also because they hail from material which is so ill-assorted that they are not forthwith comparable.

To a certain extent this fact can be traced to the neglect of some writers to distinguish between the various forms of glaucoma. To be sure, secondary glaucomas are, as a rule, kept by themselves, and this is usually the case also with glaucoma infantum and, perhaps, glaucoma juvenile. Glaucoma simplex and congestive glaucoma are, however, often lumped together. Hence the difficulty in comparing data from different countries. Most statistics show wide fluctuations in the relationship between glaucoma simplex and congestive glaucoma, the one being dominant in certain areas, the other elsewhere. At any rate, it would seem that congestive glaucoma is particularly common in southern countries, certainly more common than in the North where glaucoma simplex is by far the more common form.

My object in presenting certain figures illustrative of conditions in Norway, compared with data I have obtained elsewhere, is not primarily to contribute a

new name or new figures to the long series of earlier statistics. I believe that my Norwegian data may prove deserving of notice and may, perhaps, help to clarify certain problems because they are large in comparison with the figures presented by many other investigators. Besides, my data are so uniform that they should reflect with considerable accuracy the conditions with which we are dealing. As with all statistics, however, the numerical results must be treated critically if we are to avoid drawing false conclusions from them. I would therefore make certain reservations with regard to some of my figures.

SEX INCIDENCE OF GLAUCOMA

My material is derived from the University Eye Clinic in Oslo, and it belongs to the period, 1920 to 1939. During these 20 years, 24,127 patients were admitted to the Eye Department, 13,334 men and 10,793 women. The ratio of men to women was 55.3 to 44.7 percent.

This apparent preponderance of men patients does not make it at once permissible to conclude that eye diseases serious enough to require hospital treatment are more frequent in men than in women in Norway. In the first place, the University Eye Clinic has always had more beds for men than for women. This condition reflects the experience that there really is greater need for beds for men. The capacity of the Eye Department has always, right up to the abnormal conditions during the war, been so great that it has, on the whole, been able to accept all the patients for whom applications for admission have been made. The difference in the numbers of beds available for men and women has, therefore, had scarcely

* From The University Eye Clinic, Prof. Birger Malling, M.D., Chief.

any influence on the relative number of men and women patients admitted.

Another factor to be taken into account concerns the patients whose eye diseases may require hospital treatment, but who remain at home and to some extent at work. For various reasons they do not seek medical advice, or they beg to be excused, or they flatly refuse admission to hospital. It is probable that most such patients are women. For, once a man is so ill that he must remain at home, away from his work, it is seldom difficult to persuade him to go into a hospital. As a rule, a woman must be much embarrassed by eye disease before she completely abandons work at home. Instead of submitting to complete idleness in a hospital, she often remains ailing at home. I consider, therefore, that the figures, 13,334 for men and 10,793 for women, correctly express the relative need of the two sexes for hospital beds for eye disease. However, I doubt if they reflect the true frequency of serious eye disease in the community.

INCIDENCE IN LITERATURE

What of the incidence of glaucoma in the two sexes? The information on this score which I have found in the literature has given me no clear picture.

In *Nordisk Lærebok i Oft.* (1936) we read that: "the predisposition is much the same for both sexes, but it is perhaps somewhat greater for women, particularly in the case of acute glaucoma." *Kurzes Handbuch* (1931) quotes Priestley Smith, according to whom women are in the majority in the ratio of 6 to 5. Schmidt-Rimpler is quoted as putting this ratio at 5 to 4. Luge states that 207 of 300 patients were women. In Beren's *The Eye and Its Diseases* (1936) it is stated that the condition is found somewhat more frequently in women than in men in about the ratio of 6 to 4. In *Traité d'Ophthalmologie* (1938), Morax is

quoted as saying that most authorities believe that chronic glaucoma is about equally common in the two sexes.

In his book on glaucoma (Graefe-Saemisch, 1933), Peters quotes several statistics including those of Schmidt-Rimpler, but he also writes that, according to other authorities, men are more susceptible than women to this disease. He does not, however, give any figures. He goes on to say that Neuffer in Tübingen finds women patients in the majority. He also refers to two writers who have come to conflicting conclusions. Rohner (Basel, 1927) believes that there is no difference between the sexes up to the age of 65 years, after which women are in the majority (396 cases). Luge (1929), on the other hand, found women in the majority, particularly after the menopause. In higher age groups, however, the glaucoma rate was again highest in men!

Elliot (1922) also quotes several of the above-mentioned writers as well as Kogashima, who found glaucoma more frequent in women than in men in the ratio of 62 to 38 percent. Elliot says, however, that in the chronic, noninflammatory forms, the incidence in men may, perhaps, be greater by a small margin.

It will thus be seen that the literature gives us an exceedingly nebulous picture with regard to the sex incidence of glaucoma. This confusion arises from the fact that many writers do not distinguish in their statistics between glaucoma simplex and congestive glaucoma. All who have kept the two conditions separate agree that congestive glaucoma at any rate affects women more often than men.

INCIDENCE IN NORWAY

How do matters stand here in Norway? Taking glaucoma simplex first, I note that it was diagnosed in 2,024 of the 24,127 patients admitted to the eye clinic; that is, in almost 8.4 percent. Of these 2,024 patients, 1,261 (62.3 percent) were

men and 763 (37.7 percent) were women. These figures come from the annual reports of the department. Among them there may be a certain number of patients admitted to the department on several occasions for treatment of the other eye, for reoperation, and the like. On each occasion they received a new case record number and were thus counted as new patients each time. To ascertain if this duplication is of any importance, I have made a direct count of 1,012 patients, and have found 637 of them to be men and 375 women—figures in exact conformity with those of the annual reports. The men were so much in the majority that it cannot simply be due to the greater number of beds for them.

We should also note that glaucoma patients were never refused admission to the department. To be sure, applications on behalf of glaucoma patients for admission are sometimes made under other diagnoses, but this source of error can hardly have played any important part, since we may safely assume that any mistaken diagnoses were equally distributed between the two sexes. It is my conviction, therefore, that the 1,261 cases of glaucoma simplex among men and the 763 cases among women give us an approximately correct impression concerning the distribution of glaucoma simplex between the two sexes in Norway.

The larger number of men becomes further emphasized when we recall that women are in the majority in the age groups in which glaucoma occurs. According to official Norwegian statistics, the census of 1930 showed that, over the age of 50 years, the ratio of men to women was 45.5 to 54.5 percent.

Of 142 patients with bilateral glaucoma, with absolute glaucoma in one eye, there were 96 men and 46 women, and among 118 patients with *nearly* abso-

lute glaucoma of the worse eye, with vision of light perception only or finger counting under 2 meters, there were 82 men and 36 women. Thus, among a total of 260 patients with absolute or nearly absolute glaucoma of the worse eye, there were 178 men (68 percent) and 82 women (32 percent). These figures tally very well with the ratio of men to women in the entire study.

When we consider the cases of congestive glaucoma, we find another state of affairs. Of the total of 143 patients treated for this condition in the Eye Clinic in the period 1920 to 1939, 51 were men and 92 were women, a ratio of 36 percent to 64 percent. In other words, we have here almost the opposite of what we found in glaucoma simplex. However, one of the few points on which all writers agree is that women are more subject to congestive glaucoma than men.

The various statistics show great discrepancies with regard to the relative frequency of glaucoma simplex and congestive glaucoma. This is so to some extent because of an uncertain nomenclature. The usual classification is as follows:

1. Acute congestive glaucoma or merely acute glaucoma.
2. Chronic congestive glaucoma.
3. Chronic glaucoma simplex or merely glaucoma simplex. (Sometimes we find a special group.)
4. Absolute glaucoma.

The term applied to the first group is clear and cannot be misunderstood. As a rule, the diagnosis is not difficult, at any rate not if it is possible to examine the patient and to obtain a case history with its record of typical attacks. The shallow anterior chamber and the lack of exfoliation are also guides to the diagnosis.

Chronic congestive glaucoma, the term applied to the second group, expresses a

vague conception. It may include genuinely acute forms which lack the usual stormy course of an attack. It usually covers those cases of glaucoma simplex which have begun insidiously, which have gradually developed an ever-increasing pressure, and which have finally presented more or less marked manifestations of chronic congestion and inflammatory phenomena. The English term "chronic uncompensated glaucoma" gives a correct picture of this condition without taking the onset of the disease into consideration. Presumably certain cases of secondary glaucoma, notably when they follow thrombosis of the central vein, will also be included in this group.

Group 3 includes those cases we are accustomed to describe merely as glaucoma simplex, and this designation is, as a rule, clear and straightforward.

The term applied to Group 4, absolute glaucoma, is an unfortunate one, for it merely signifies a stage in the development of the disease and does not tell us the form of glaucoma with which we are confronted. I believe that the cases usually included under the diagnosis of absolute glaucoma represent, in most instances, glaucoma simplex in a far advanced stage but without manifestations of irritation. When there are signs of irritation, the diagnosis is often chronic congestive glaucoma. The cases of acute glaucoma leading to blindness are, as a rule, easily recognized and are accordingly given the diagnosis of acute glaucoma.

In his statistical analysis, Ahlström gives the frequency of the various forms of glaucoma as follows:

<i>Classification</i>	<i>Percent</i>
1. Prodromal conditions in	3.6
2. Acute glaucoma	6.5
3. Chronic congestive glaucoma	24.9
4. Glaucoma simplex	41.7
5. Absolute glaucoma	23.3

The terms employed for the first and last groups are primarily indicative of stages of the disease; whereas, the terms in the three other groups refer to the clinical manifestations of the disease. The groups cannot, therefore, be compared with each other without further delineation.

A classification resembling Ahlström's is adopted by v. Grosz of Budapest in his large statistical study, extending over 30 years, of 52,032 patients, 5,958 of whom (11.4 percent) suffered from glaucoma. He presented the following groups:

<i>Classification</i>	<i>Num- ber</i>	<i>Per- cent</i>
1. Glaucoma inflammatorium in a prodromal stage.	453	7.8
2. Glaucoma inflammatorium acutum.	792	13.3
3. Glaucoma inflammatorium chronicum	2,967	49.7
4. Glaucoma absolutum.	1,124	18.8
5. Glaucoma simplex.	622	10.4

In this classification Groups 1 and 2 can be fused together. Group 3 evidently belongs, in the main, to Group 5, as does Group 4. By limiting ourselves to two groups we shall, at any rate, not include too many cases in the glaucoma inflammatorium acutum group.

These statistics show that the relationship of glaucoma inflammatorium to glaucoma simplex varies greatly. While, according to Ahlström, glaucoma acutum is responsible for 6.5 percent (at most 10.1 percent) of all the cases of glaucoma, the corresponding figures, according to v. Grosz, are 13.3 percent (or at the most 21.1 percent).

In his *The Eye and Its Diseases*, Berens says that glaucoma simplex is about 10 times as common as the uncompensated forms of glaucoma, but in a later table he quotes figures from his own practice showing 77 cases of compensated, 33 acute uncompensated, and 44 chronic uncompensated.

My own statistics show: Glaucoma inflammatorium, 143 cases of 6.6 percent; glaucoma simplex, 2,024 cases or 93.4 percent. These figures tally quite well with Ahlström's, and this would be expected since the ethnical background of Ahlström's patients and mine is similar; whereas, v. Grosz's patients come from southern and eastern countries and belong to other ethnical groups.

REFRACTIVE ERRORS IN GLAUCOMA

What are the most common refraction findings in patients who develop glaucoma? Much information is available on this, but the various textbooks deal, to a large extent, with statistics from the same authors, and figures are either not mentioned or are comparatively small.

A statement in *Nordisk Lærebok* says: "... among refraction findings hyperopia seems to predispose to stasis glaucoma. Simple glaucoma appears to occur independently of the state of refraction of the eye."

According to a statement in *Traité d'Ophthalmologie*, Gilbert in Munich found hypermetropia in 38 percent of his cases and emmetropia or myopia in 62 percent (71 cases), but hypermetropia was found in 77 percent of the cases of glaucoma acutum. Morax insists that inverse astigmatism is of some importance, and he recommends pressure control when this error of refraction is found.

Elliot says: "Hyperopia is the commonest refraction error met with in eyes affected with primary glaucoma." He quotes Gilbert and also Lange, who found myopia in 43 percent of his cases. According to *Kurzes Handbuch*, hypermetropic eyes are quite definitely more often attacked by glaucoma than myopic eyes. Peters remarks that hypermetropia is said to have a causal relationship to glaucoma because of the smallness of the

cornea, the narrower filtration angle, and the greater rigidity of the sclera. But myopia also occurs frequently (cit. Lange and Gilbert).

In his textbook, Berens says: "The refractive error of the eye is of interest, as it was formerly believed that only hyperopic eyes were subject to compensated glaucoma. We now know that this view is erroneous and that, although the anatomic build of the hyperopic eye renders it more susceptible to glaucoma than that of the myopic eye, other factors are of greater importance."

He then proceeds to relate his own experience with his last 188 cases of glaucoma, only 77 of which were "compensated." Among these 77 cases were 50 of hyperopia (65 percent), 19 were cases of myopia (25 percent), and 8 showed mixed astigmatism (10 percent). Thus, strangely enough, he had no case of emmetropia. Among his cases of hyperopia there were 24 with less than +1.50D. of hyperopia, and among his cases of myopia there were 15 with less than 6.00D. of myopia.

In the opinion of certain writers, however, the development of glaucoma in persons with myopia is so rare as to inspire the publishing of several cases in which special reference is made to the combination of the two conditions. In 1929, Schenk stated that glaucoma seldom occurs in myopics; whereas, in the same year Meyerhofer stated that glaucoma and myopia often occur together in Egypt (in 12 out of 183 cases).

For my own part, I have kept a record of the refractive errors in glaucoma only during the 11 years, 1928 to 1939. The refraction was in every case measured before operation by Donders' subjective method. During this period, refraction conditions of 1,417 eyes suffering from glaucoma simplex were recorded. The refraction conditions were as follows:

Type	Percent
Hyperopia	25.6
Emmetropia	50.7
Myopia	19.1
Astigmatism	4.6

I have also divided up these cases into smaller groups so as to show the occurrence of the more marked errors of refraction (table 1).

Table 1 shows that most of the cases group themselves about emmetropia

in about 30 percent of these cases; hypermetropia in about 55 percent; and myopia in about 15 percent. A refraction of +1.00D. is counted as hypermetropia. If his curve is correct, my figures do not show that persons with hypermetropia are particularly subject to glaucoma simplex, but rather the reverse; that is, that they are less likely to contract glaucoma than persons with other refractive errors. To facilitate a comparison, I have placed Herrnheiser's figures for refraction con-

TABLE 1
REFRACTIVE CONDITIONS IN GLAUCOMA SIMPLEX

Refractive Error	More Than +2. D.	Less Than +2. D.	Between +.5 D. - .5 D.	Less Than -2. D.	Less Than -6. D.	More Than -6. D.	Astigmatism		
							+	-	Inverse
Number of Patients	79	288	719	178	78	23	23	18	29
Percent	5.5	20.1	50.7	12	5.4	1.6	1.6	1.2	2.0

which is the dominant refraction condition in glaucomatous eyes. The exaggerated errors of refraction are represented by small groups. It is particularly striking that the hypermetropic group is so small.

What is the frequency of the various errors of refraction in a normal group? Many investigations have been undertaken of refraction conditions in different groups of the community and also in certain age groups, but I have not found any investigation giving a straightforward account of the various refraction conditions in the higher age groups. However, Herrnheiser (*Kurzes Handbuch*) has presented a curve showing the distribution of refraction conditions in various age groups. After the age of 30 years, conditions are more or less constant, but with a tendency to an approach to emmetropia after the age of 70 years in the subjects of both myopia and emmetropia. He says that emmetropia occurs

conditions in normal groups beside my figures for these conditions in glaucoma groups.

Normal	Glaucoma
(Herrnheiser)	(Holst)
Hypermetropia, 55.0%	Hypermetropia, 25.6%
Emmetropia, 30.0%	Emmetropia, 50.7%
Myopia, 15.0%	Myopia, 19.0%

Here it is remarkable that the incidence of myopia is higher among glaucoma patients than in a normal group; whereas, hypermetropia is only half as frequent among glaucoma patients as in a normal community.

It is conceivable that my figures are vitiated by several sources of error. As already pointed out, the refraction was measured before operation, but patients in several cases had suffered from glaucoma for some time and had, as a rule, been treated with pilocarpine. Although we were dealing with elderly patients, some of them could have retained a little

accommodation. In such cases, pilocarpine may have induced an "accommodation cramp" which can simulate myopia. Further, it is possible that, in some cases, the glaucoma may have led to degenerative changes in the eye, such as early cataract, which betrayed themselves as a lenticular myopia. My material does not provide sufficient information to determine whether many of my patients have become myopic as the result of pilocarpine medication or through the progression of

showed inverse astigmatism seems to support Morax's assumption that this condition predisposes to glaucoma. We should, therefore, do well to follow his advice and carefully supervise the ocular pressure of patients suffering from inverse astigmatism.

Unfortunately, with regard to congestive glaucoma, I have information concerning the refractions of only 59 patients with a total of 75 eyes presenting this condition. Their refractions are

TABLE 2
REFRACTIVE CONDITIONS IN CONGESTIVE GLAUCOMA

Refractive Error	Hypermetropia			Emmetropia	Myopia		Unknown
	More Than +6.00 D.	More Than +2.00 D.	Less Than +2.00 D.		Less Than -6.00 D.	More Than -6.00 D.	
Number of Eyes	3	11	19	25	6	2	9
Total (75 Eyes)	33			25	8		9

the glaucoma, but the shifting of the refractive conditions from hypermetropia to emmetropia and myopia could have glaucoma as a causal or predisposing factor. Nor can any definite answer to this question be obtained by investigating the refractions of patients with unilateral glaucoma and anisometropia.

In 80 of 97 cases of unilateral glaucoma and anisometropia, the refraction showed the glaucomatous eye to be more myopic than that of the healthy eye, but, as already pointed out, we do not know what the refraction of the glaucomatous eye was *before* the manifestation of signs of glaucoma.

It will be noted (table 1) that I found astigmatism in 4.8 percent of the cases studied (myopic, regular astigmatism a little more frequently than hypermetropic, regular astigmatism). The fact that as great a proportion as 2 percent of my cases

shown in Table 2. The figures in Table 2 do not differ greatly from Herrnheiser's normal figures. If we are to draw any conclusion whatever from this small number of cases, it would seem that hypermetropia plays a considerably more important part in congestive glaucoma than in glaucoma simplex, while the combination of myopia and congestive glaucoma is more rare than that of myopia and glaucoma simplex.

FIRST EYE TO BE ATTACKED

Which eye is most frequently the first to be attacked by glaucoma? According to Schmidt-Rimpler, the right eye is not only more often the first to be involved but also, when the disease is confined to one eye, the right is most often that one eye.

When the patient presents himself with advanced bilateral glaucoma, it is not

always easy, however, to say which was the first eye to be attacked. Frequently, he notices definite signs of the disease in one eye before the other, and the development of glaucoma is often marked by such different stages in the two eyes that we are justified in concluding that it began in the eye in which the disease is most advanced. A record of 1,040 patients kept by me during the last 11 years shows that glaucoma began in the right eye in 390 cases, and in the left eye in 486 cases; whereas, in 164 cases information on this point was lacking for various reasons. These figures do not tally with those given by Schmidt-Rimpler, but they do agree with the records of the University Eye Clinic in Oslo for the period 1928 to 1939 when a greater number of left eyes (375) than right eyes (345) were operated for glaucoma simplex. The small difference between these two figures *may*, to a certain extent, be explained by this hypothesis:

If it is true that glaucoma more frequently attacks the left eye before it does the right eye, *then* more left than right eyes are the seat of absolute glaucoma and are *not* operated because the condition in the left eye is hopeless; whereas, the right eye, still possessing useful vision, is operated on.

This hypothesis can, moreover, be substantiated by facts. Of 189 eyes presenting absolute glaucoma, or nearly absolute, and not subjected to any glaucoma operation, 102 were left eyes and 87 were right eyes. Further, among 196 patients with unilateral glaucoma, the left eye was involved in 119 cases, the right eye in 77. These figures would seem to indicate that the left eye is more prone to glaucoma than the right, but why this is so I cannot say.

EXFOLIATION OF LENS CAPSULE

The presence or absence of exfoliation

of the lens capsule is of great interest in cases of glaucoma. Here in Norway, Hörven's researches in this field have attracted special attention. He says that "we can take it as proved that between 60 and 70 percent of the patients presenting exfoliation suffer at the same time from glaucoma." Indeed, Vogt has found glaucoma in as great a proportion as 75 percent of his cases of exfoliation. Several other writers mention similar figures.

How many glaucoma patients suffer from exfoliation? Data concerning this point are most varied. According to Hörven, various writers put this rate at 8 to 9 percent (Vogt, Blaickner) while others put it at 40 to 50 percent (Malling, Baumgart, Lindberg). Hörven, himself, found that 85 percent of his 150 glaucoma patients suffered from exfoliation. However, it is surprising how little interest has been taken in this matter and how seldom exfoliation is demonstrated. In certain hospitals the lists of diagnoses include a special heading, "glaucoma capsulare," under which very modest figures are to be found.

In my study, examinations for exfoliation have been carried out only since 1936 (after the appearance of Hörven's thesis for the degree of Doctor of Medicine). During this period information about exfoliation has been obtained in the study of 459 cases of glaucoma. It was found in 375 cases (82 percent). This observation falls well in line with Hörven's. All the patients were examined in focal illumination with Hartnack's loupe. Most of the patients, who yielded negative findings on this examination, were also examined more closely with a slit-lamp; some, but not all, under glaucosan mydriasis. It is conceivable that a more consistent and detailed examination would have shown still more cases of exfoliation.

It is noteworthy that among these 459

patients, there were 53 with unilateral glaucoma in whom exfoliation was found in one eye only, and that one eye was invariably the glaucomatous eye. We are, therefore, fully justified in assuming a close association between exfoliation of the lens capsule and the condition we call glaucoma simplex.

Unfortunately, my statistics regarding any association existing between congestive glaucoma and exfoliation are most incomplete. In only 10 cases was an examination for exfoliation recorded. In none of these 10 cases was exfoliation demonstrated.

SUMMARY

At the University Eye Clinic in Oslo, in the period 1920 to 1939, there were 24,127 admissions, 13,334 patients (55.3 percent) were men, and 10,793 (44.7 percent) were women. Among these 24,127 admissions were 2,024 cases (8.4 percent), of glaucoma simplex; 1,261 were men (62.3 percent), and 763 women (37.7 percent). The fact that men greatly outnumbered women is more surprising when it is remembered that in the age group (over 50 years) in which the incidence of glaucoma is most high, the percentage of men to women is 45.5 to 54.5.

Of the 143 patients suffering from congestive glaucoma, 36 percent were men, 64 percent, women; that is, a ratio almost the reverse of that for glaucoma simplex.

A comparison of the frequency of the two forms of glaucoma shows that glaucoma simplex constituted 93.4 percent of all the cases; whereas congestive glaucoma constituted only 6.6 percent.

With regard to the refractions of pa-

tients with glaucoma simplex, hypermetropia was found in fully 25 percent; emmetropia in fully 50 percent; and myopia in 19 percent; and almost 5 percent were astigmatic. These figures, when compared with Herrnheiser's "normal curve" show that, in the present material, there were only half as many subjects of hypermetropia as one can expect to find in a normal population; that there were more cases of myopia; and that the preponderance of emmetropia was very marked.

The information provided by the present study fails to show whether the shifting of refraction in the direction of myopia is a predisposing cause of glaucoma, or a consequence of it, or the result of treatment given for it (changes in the lens, pilocarpine).

Inverse astigmatism was found in as great a proportion as 2 percent.

Among 1,040 glaucoma patients, there were 390 whose disease began first in the right eye, and 486 whose disease began first in the left eye; whereas, in the remaining 164 cases information was not forthcoming as to which eye was first attacked.

In 459 cases an examination was undertaken for exfoliation of the lens capsule which was found in 375 cases (82 percent).

In the 53 cases of unilateral glaucoma in which exfoliation was found on only one side, it was always found in the glaucomatous eye only. The reverse condition, with exfoliation in the healthy eye, but not in the glaucomatous eye, was never observed.

Pilestredet 28.

THE DIAGNOSIS OF EARLY GLAUCOMA*

HENDRIE W. GRANT
St. Paul, Minnesota

In the presence of symptoms of unrelieved asthenopia, subnormal or unequal accommodation, a variation of more than a few mm. in the tension of the two eyes, sclerosis of the lens nucleus, or the history of glaucoma in the family, one should institute a searching examination for evidence of early glaucoma. Contraction of the peripheral fields and cupping of the optic nerve are late symptoms. Although routine determination of the ocular tension may be found to be normal, enlargement of the blindspot is present if the tension has been recently elevated. At this early stage, when paracentral field changes are present, the process may still be a reversible one, but normally does not occur until the tension has been normal for a considerable period of time. Since in early glaucoma the tension may be elevated for only a few hours each day, enlargement of the blindspot is found in the presence of normal daytime tension. The evaluation of the changes from the normal to the enlarged blindspot, the reversibility of the enlargement, along with the details of the study are here described.

METHODS FOR DIAGNOSIS

Many methods for the diagnosis of early glaucoma have been described, especially methods of increasing the intraocular pressure. In such instances the diagnosis is made upon the increased pressure alone. These methods are: massage test, Knapp, 1912; dark-room test, Seidel, 1914; decubitus test, Köllner, 1916; adrenalin test, Knapp, 1921; fluorescein,

Thiel, 1922; caffeine test, Wegner, 1925; drinking test, Schmidt, 1928; venous-congestion test, Wegner, 1930; paracentesis test, Kronfeld, 1930; reading test, Gradle, 1931; mydriasis test.

Ferree, Rand, and Sloan have shown the sensitivity of the paracentral area to scotomas and the value of red and green test objects in individuals suffering from frank glaucoma with constantly elevated tension (sometimes controlled with miotics).

Sloan described the early paracentral field changes in early glaucoma, principally arcuate or sickle type of scotomas. These were divided into (1) scotomas which encircled the fixation point, (2) relative scotomas present without absolute scotomas, (3) scotomas which decreased or disappeared with the use of pilocarpine. Sloan further confirmed the opinion of Samojloff that the sickle type of scotoma disappears quickly after the use of pilocarpine but only after prolonged use in more advanced cases.

Sloan, Peter, and Traquair have discussed the association of the arcuate scotoma with the blindspot, and its isolation from the blindspot. On the other hand, Thomasson found that an isolated scotoma is never an early manifestation of glaucoma, all early scotoma being attached to the blindspot itself.

This paper presents data on 27 cases of increased intraocular pressure without evidence of cupping of the optic nerve or changes in the peripheral field, one case of slight cupping, two cases of shallow anterior chambers, and three cases without increased tension. These patients, observed over a period of 6 months to 7½ years, have had frequent

*Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

determinations of the ocular tension plus detailed study of the blindspots. Every case of glaucoma with cupping has been eliminated except the one case previously mentioned.

TONOMETRIC READINGS

In the diagnosis of early glaucoma there seem to be several difficulties in taking tonometric readings. It is not easy to teach residents and ophthalmic assist-

progressive presbyopia, unequal accommodation, asthenopia not relieved by adequate correction, difficulty in reading in the early morning, the presence of nuclear sclerosis, and blindness in the mothers of three of the patients were some of the reasons for study.

The tonometer used was of the Gradle-Schiotz type. It was sent to a standardizing station and found to be in good mechanical order. Reconversion tables were

Fig. 1 (Grant). Changes in blindspot in early glaucoma as shown in several cases without cupping of the optic nerve but having increased tension.

ants the art of taking tonometric readings, so wide variations occur. Slight variations of 3 to 5 mm. cause marked changes in the paracentral field; whereas, it may be difficult to make a diagnosis of glaucoma on a rise of from 3 to 5 mm. of intraocular pressure. Evans has stated that careful mapping of scotomas is a much more sensitive indication of increased intraocular pressure than any tonometric measurement. It is believed also that residents and assistants obtain more uniform field studies than tonometric readings, and that both are essential in establishing a diagnosis of glaucoma.

Many reasons besides routine tonometric readings were present in this group for detailed field studies. Rapidly

never received and the tonometer was standardized as follows: Many routine tests were performed on the blindspot with tensions varying from 20 mm. upward. It was found that no change occurred in the blindspot with a 1-mm. test object on the tangent screen at one meter with tensions up to and including 28 mm., with three exceptions noted. Similar normals were present for 4-, 8-, and 12-mm. red test objects at one meter. When, however, the tension was above 28 mm., demonstrable changes were present in the paracentral field. I have observed also that all individuals seemed to have the same limit of normal tension.

ENLARGEMENT OF BLINDSPOT

The earliest change noted is a relative

enlargement of the blindspot which may be observed for red test objects of 4, 8, and 12 mm. The earliest absolute changes are winglike scotomas which appear on the temporal sides of the blindspot either

the blindspot may be almost round. At the onset these scotomas appear and disappear with the rise and fall of tension, in some cases disappearing completely if the tension falls to normal and remains so. Im-

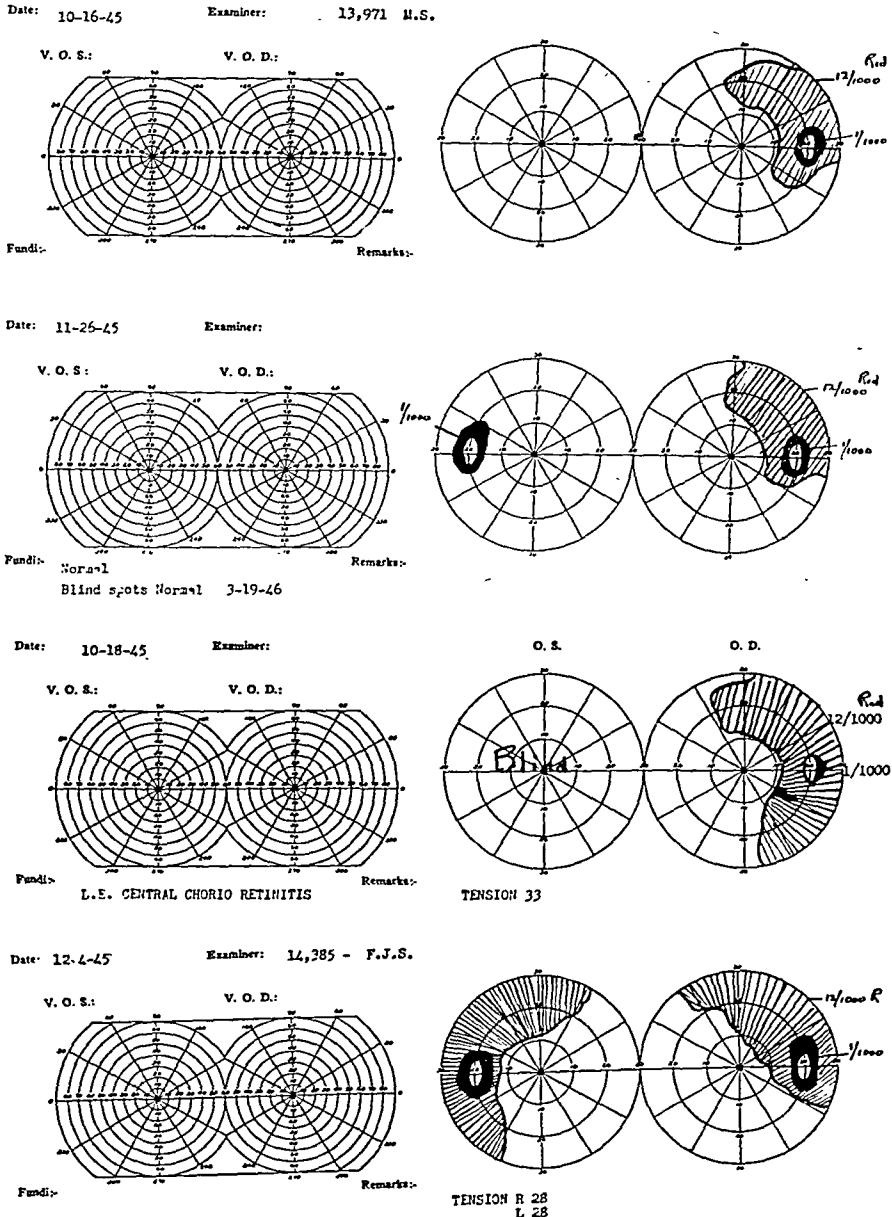

Fig. 2, Part 1 (Grant). Changes in blindspot for $1\frac{1}{2}$ mm. white and 12 mm. red on a standard 1-mm. screen.

as tongue-like protuberances or as a gentle elongated enlargement along the whole side. The upper and lower poles remain normal and may have a very pointed appearance if there is marked widening, or

provement, however, occurs very slowly, and several weeks or months may elapse before normalcy is reached. Small tongue-like elongations appear at the upper and lower poles only after lateral enlargement

has occurred. It would appear that the coalescence of these small winglike and tonguelike scotomas ultimately causes the permanent irregular enlargement of the blindspot. No sickle or arcuate type of scotomas appears attached to or free from the normal blindspot, only on the enlarged blindspot. In the early or late stages, the sickle type is separated from the blind-

strated in individuals who have normal tension for most of the day with elevation for only a few hours in the early morning, or elevated artificially by one of the previously suggested methods. I have found, however, that checking of the tension and blindspots very early in the morning as soon as the patient is out of bed will, in most instances, eliminate the

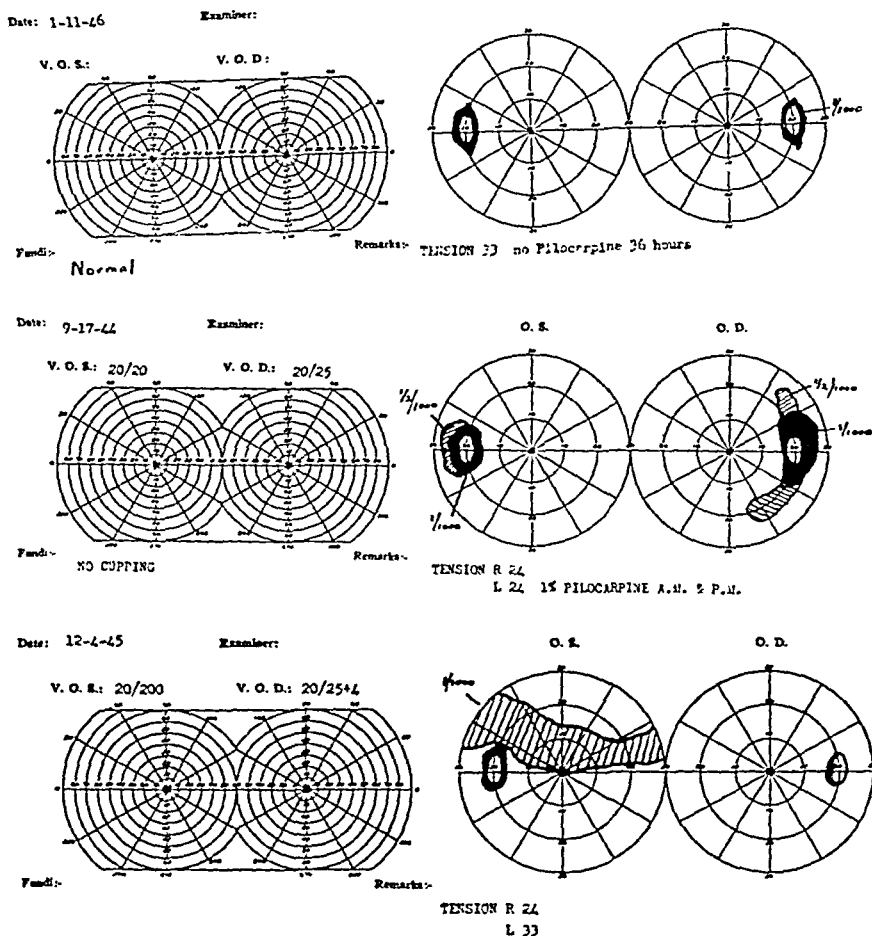

Fig. 2, Part 2 (Grant). Changes in blindspot for $1\frac{1}{2}$ mm. white and 12 mm. red on standard 1-mm. screen.

spot by a small area of vision, especially so if these appear for an hour or so when the tension is elevated, and disappear with the reduction of tension. Only when the condition is more advanced is the arcuate scotoma attached to the blindspot itself. These observations concur with those of Thomasson.

These early changes are easily demon-

nstrated in individuals who have normal tension for most of the day with elevation for only a few hours in the early morning, or elevated artificially by one of the previously suggested methods.

CASE REPORTS

MYDRIASIS TEST

The mydriasis test produces alarming changes in the blindspot in one hour, when positive, as is illustrated by the following cases:

Fig. 4 (Grant). Marked increase in scotoma after use of paredrine showing very slow return to normal.

Case 1. M.-T., (1,291), a woman, aged 70 years, has been under observation since 1934. In 1937 considerable sclerosis of the lens nucleus with many streaks in the periphery of the lens was noted. In October, 1945, the vision was reduced to 20/30 in each eye and the tension was normal at noon. One-percent paredrine was instilled in each eye, causing a rise of pressure to: R.E. 43 mm. Hg; L.E., 33 mm. The paracentral field changes at

ELEVATION OF TENSION FOR A FEW HOURS

That a slight increase in intraocular pressure for a few hours each day may occur over a period of years and produce marked changes is borne out by the following case:

Case 3. C. B. R., a physician, aged 65 years, was first seen in 1933. He had been struck in the left eye six years previously by a piece of copper from an exploding rifle shell, which produced an

Fig. 5 (Grant). Blindspots of patient 7½ years after observation without cupping of the optic nerve but with marked increase of tension.

that time showed a very marked enlargement and remained so in spite of reducing the tension to 24 mm. in each eye after the lapse of one hour. The blindspots remained enlarged considerably above normal until January 23, 1946, approximately a lapse of three months before they could be considered normal. No cupping of the optic nerve has been present at any time.

Case 2. G. B., (14,167), a woman, aged 67 years, examined in October, 1945, showed a vision of: R.E., 8/200; L.E., 20/25, corrected. The fundus of the right eye showed a retinitis of hypertension, Grade 2, with newly formed vessels on the optic nerve due to a previous vascular accident. There was a slight enlargement of the left blindspot. Paredrine instilled for fundus examination increased the tension to 38 mm. with a marked increase in the size of the scotoma which gradually became normal in May, 1946.

open wound of the conjunctiva but no foreign body was ever found. His vision was 20/20 in each eye and no note was made except a possible slight cupping of the left optic nerve. The tension was: R.E., 20 mm. Hg; L.E., 24 mm. Next observation was in June, 1945, when the vision was: R.E., 20/20; L.E., 20/25. Tension was: R.E. 26 mm. Hg; L.E. 26 mm. Fundi showed slight cupping of both optic nerves. The fields showed slight peripheral contraction, enlargement of both blindspots.

On December 3, 1945, tension was: R.E., 28 mm. Hg; L.E., 28 mm. One hour after the instillation of paredrine, the readings were: R.E., 20 mm. Hg; L.E., 28 mm. On December 5, 1945, on arising, tension was: R.E., 30 mm. Hg; L.E., 33 mm. Fields showed a sickle-type scotoma, detached from the blindspot. This blindspot disappeared in one hour.

ENLARGEMENT OF BLINDSPOT WITH NORMAL TENSION

Interest centers chiefly on those cases which Gradle calls the preglaucomatous. In the first instance of the acute congestive type, without increase in intraocular pressure, he states that paracentral field changes are absent. The following

20/20. Tension was: R.E., 55 mm. Hg; L.E., 20 mm. The tension of the right eye was reduced to 20 mm. with 2-per cent pilocarpine every half hour and an iridectomy performed on January 23rd permanently reduced the increased pressure. Records of the 24-hour tension studies of the left eye during her hospital stay

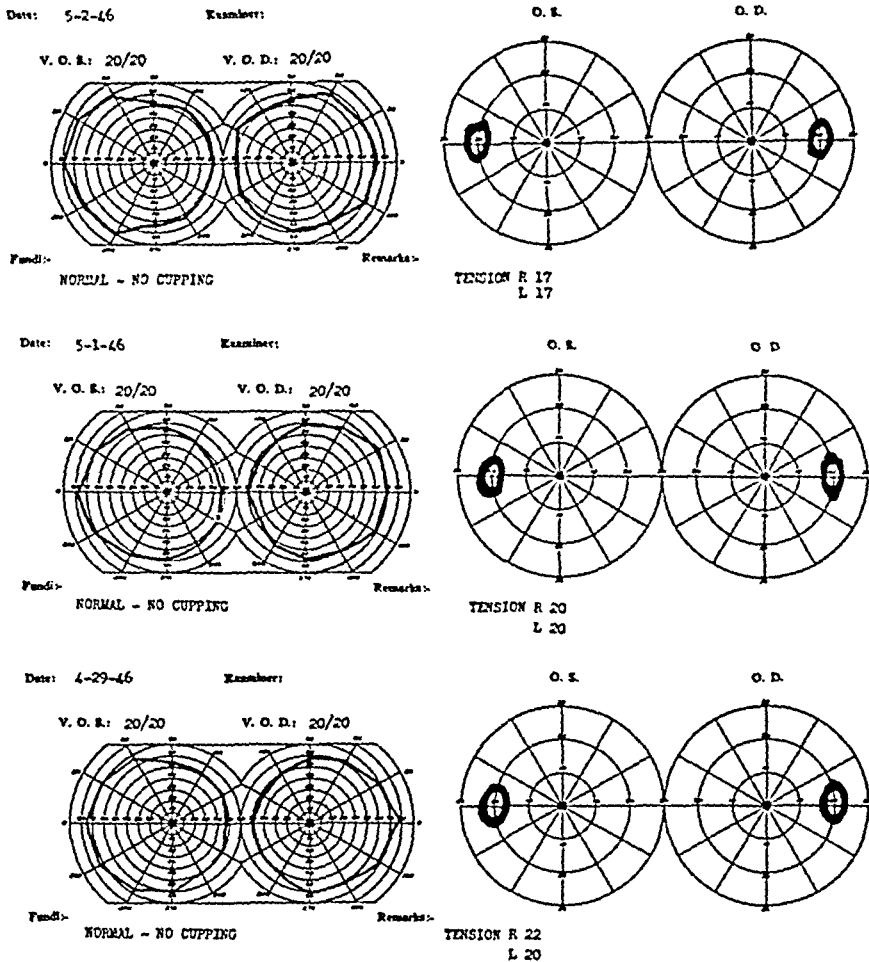

Fig. 9 (Grant). Enlargement of blindspot in three patients with symptoms of glaucoma, but with normal tension.

cases show enlargement of the blindspot with normal tension:

Case 4. J. P. K., a white woman, aged 64 years, was first seen January 19, 1945, with acute congestive glaucoma of the right eye. Symptoms simulating an acute rise in tension had been present since May, 1944. Vision: R.E., 10/200; L.E.,

did not reveal evidence of increased pressure at any time. The blindspots on January 31 were 2-2-45, 6-14-45, 8-6-45.

Case 5. McK., (14,311), a woman, aged 56 years, reported for examination in November, 1945. The corrected vision was: R.E., 20/20; L.E., 20/20. Tension before mydriasis was R.E., 20 mm. Hg;

L.E., 20 mm., and after mydriasis: R.E., 24 mm. Hg; L.E., 20 mm. Five-percent pilocarpine was then instilled in each eye. The following morning there was pain and blurred vision in the right eye which required surgery for the control of the tension. Vision was ultimately 20/20

with some reduction of the visual field. During her stay at the hospital, the tension of the left eye was normal throughout the 24-hour period and was never found to be elevated. There had, however, been symptoms suggestive of an acute rise of intraocular pressure. The cham-

ber was slightly shallow and a definite enlargement of the left blindspot was noted on discharge from the hospital, and the highest tension recorded has been 20 mm. This enlargement has persisted in spite of the use of pilocarpine twice daily.

COMMENT

Of the chronic noncongestive type of questionable glaucoma, three cases are here presented. The ages of the patients were 43, 45, and 59 years. All complained of fatigue with adequate correction of the refractive error. In two there was unequal accommodation, and in the other the accommodation was a very low normal. All three had enlarged blindspots, normal tension, and normal fundi. All three were very definitely improved with 1-percent pilocarpine used twice daily and were very willing to continue because of the relief obtained. The enlargement of the blindspots is characteristic of the group with increased tension, and the two with shallow anterior chambers. No change has been noted in the size of the blindspot in the course of a few months' treatment.

There are many questions. Is this a glaucoma with changes due to low pressure? Are the changes in the blindspot due to pressure? Has the tension been elevated above normal at some previous time? These questions can only be answered by long-continued observation and study.

SUMMARY

The following cases are presented: An analysis of the enlarged blindspot in 27 cases of early glaucoma without cupping of the optic nerve or peripheral field changes. A case of slight cupping of the optic nerve with increased tension found on only one occasion in the early morning with characteristic changes of glaucoma. Two cases of acute congestive glaucoma, with shallow anterior chamber in the fellow eye, with normal tension and an enlargement of the blindspot. Three cases of enlarged blindspot in persons with symptoms suggestive of glaucoma, without evidence of increased intraocular pressure. Study of the blindspot is a valuable aid to the study, progress, and diagnosis of early glaucoma.

THE DISSATISFIED REFRACTION PATIENT*

C. A. VEASEY, JR., M.D.

Spokane, Washington

Study of the physical laws of refraction is an exact science. A less scientific procedure is the estimation of errors of ocular refraction. In this act, colloquially and ungrammatically referred to as "refracting a patient," the introduction of the subjective element involves fallibility. In the main, the objectives of clinical refraction are: (1) improvement in visual acuity, in which case the result of subjective improvement can be expressed by an objective formula; and (2) the relief of completely subjective symptoms. In the last instance the prescribing of corrective lenses becomes an art entailing its proper modicum of woes.

As practitioners of medicine our obligation to the patient is not fulfilled until he is relieved of his symptoms and satisfied in his own mind. The mere issuance of a written optical formula accompanied by certain brief instructions may possibly result in a cure; but this discussion concerns itself with the patient who is still unhappy and occasionally belligerent. Let us treat the patient as an ill individual; not merely compensate for his refractive error. We are, let us hope, physicians, not physicists.

On the lower plane of economics these patients deserve special consideration. A loquacious and dissatisfied patient does one's practice considerable disservice, especially in smaller communities. It is business folly to refuse to see these people or to brush them off with a curt statement that "your glasses are correct and you will have to get used to them."

In actual practice the receptionist and,

embarrassingly, those in the reception room are the first to hear of one's failure. The receptionist should receive the news sympathetically and diplomatically usher the patient to more secluded surroundings. Here he may be allowed to cool off, but not too long, for he may be irked by delay.

The complainant frequently begins with a deluge of generalities, sometimes highly seasoned with maledictions for the glasses and opprobrium for the doctor. On receiving the patient in the consulting room, it is my practice to give him ample time to relate his woes, and I list each one. This conversational catharsis tends to relieve antagonism as well as to define specific difficulties which may be explained or corrected.

BLURRED VISION

In any complaint the first procedure is obviously to check the lenses for agreement with the prescription. This has presumably been done before they were worn but errors do occur, especially reversed axes, reversed lenses, and less frequently a totally strange correction. If the lenses are correct and the complaint is lack of visual acuity, especially if the patient claims to see better with his former correction, find out if this is so and at what distance. Not infrequently a sense of strangeness is interpreted as blurring and, if improved vision can be demonstrated, the complaint is resolved. If the vision is definitely less than when the glasses were prescribed, assuming no ocular disease, there is obviously an error. With lenses prescribed under mydriasis a further reduction in sphere may be necessary, or the axes may have

*Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

shifted, especially if the cylinders be of high degree. Too much spherical correction is more frequent with high hypermetropia, but can occur with corrections of less than $+1.00D.$, and also in low minus corrections. One patient accepting $-2.00D.$ at 6 meters found his vision for bowling impaired until another quarter was deducted. Shifting of axes after mydriasis is frequent. Both these difficulties could be avoided by routine post-mydriatic tests, but the delay, in patients living at a distance, is prohibitive.

A discrepancy between the location of a focal plane in the trial frames and the finished glasses may cause blurring with high corrections. A clue to this is furnished when the patient either pulls the glasses down on his nose or pushes them nearer his eyes to improve his vision. This is particularly true in aphakia or very high myopia. A young woman for whom I had prescribed $-18.00D.$ had to be increased to $-19.00D.$ because I had placed the test lenses too close to her eyes, resulting in undercorrection. When using high spheres, it is essential to consider which cell of the trial frame is used.

A not infrequent complaint is that the formerly better eye is now the worse eye. If, with the former correction, the vision in O.D. was 6/9 and in O.S., 6/15, and on refraction the right eye was unimproved and in the left eye 6/7.5 was obtained, the patient feels there is something wrong. An explanation of the pathologic processes will usually satisfy the patient. In intumescence of the lens, a similar complaint results when the distance acceptance is toward the minus side, thus making the reading focus more remote. The myope, especially if presbyopic, will often complain of reading difficulties if the strength of the distance correction is increased.

Often we hear the statement: "I could see all right without glasses until you

gave me these." The explanation is either that accommodative strain has been relaxed or the patient is approaching presbyopia, or a change of occupation is entailing more accurate vision. It is with difficulty, however, that one can convince the patient that the glasses have not "weakened" his eyes.

All cases of blurring are not the fault of the recently prescribed lenses. In two instances, both women, one presbyopic and one younger, the complaint was inability to read with the new glasses. The disability was real. They both required addition plus. There was a marked weakness of accommodation, in the first instance due to "nerve medicine" containing hyoscine, and in the second to gastrointestinal therapy containing atropine.

CLERICAL ERROR

If none of the above be applicable, it is necessary to suspect a clerical error. It is a great help to have a record of a previous refraction. If the patient is new to me I always neutralize his old lenses, both to avoid putting him to the expense of duplication and to find with what correction he has been unhappy. Even with assiduous attention to accuracy the human mind plays tricks especially under pressure. Mental transpositions can occur; for example, in recording axes, transposing 15° to the right of the vertical to 15° to the left of the vertical, thus recording 105° for 75° , or similarly with a horizontal axis; or transposition of the intercardinal axes. A substitution of the wrong sign should be easily found if it occurred in transcription. If it is in the original record, a comparison with former corrections furnishes the clue. If there be no former record, it is necessary to repeat the refraction. Clerical errors can cause the omission of a figure, axis 135° being recorded as 35° , or an incorrect figure in transcription such as a hastily

written 5 being read as an 8. In one instance, I discovered a $+1.75D$. add in a person 75 years of age. Obviously, I had meant a $+2.75D$. In dictation, a figure may be miscalled or misunderstood. In recording from the trial frame when more than two lenses are used, one may be overlooked. The most grievous error I have ever encountered was a reversal of 4 degrees of vertical prism! This was discovered by comparison with previous corrections.

Blurring, of course, can arise from ocular disease. The patient is usually aware of corneal opacities as they have resulted from antecedent disease or injury. Lenticular opacities, cloudy vitreous, or macular degenerative changes require explanation, and it is often difficult to convince the patient that the fault is not remediable by different lenses.

ADJUSTMENT

Passing now from blurring to discomfort, the first step is to check the adjustment of the glasses. The interpupillary distance and the optical centers must correspond, with proper decentering for reading corrections. There must be vertical compensation for facial asymmetry, and the difference in level of the lenses must be accomplished without rotation of axes. In high corrections it is useful to check the adjustment of the finished glasses by the Maddox rod with horizontal image. In high cylinders I have found it useful to check the axis of the finished glasses with the cross cylinder. Minute degrees of rotation which cannot be measured on the trial-frame scale will result in comfort or discomfort. I have the optician come to the office and make repeated checks until the point of equality is found.

Some persons are more comfortable with an incorrect P.D. One hypermetropic person with high esophoria is comfort-

able only with the lenses decentered in. This gives the effect of base-in prisms which theoretically should increase discomfort, but does not.

Complaints based on obvious mechanical difficulties we will pass over. Comfort and convenience are often increased by raising, lowering or tilting the lenses. The latter is especially true in bifocals. If, on looking down, the reading segment is progressively farther from the cornea the effective strength of the lens is increased, causing blurring or an inconveniently short focus. This is obviated by tilting the lower edge toward the face so that the radius of the eyeball plus the distance from corneal center to lens becomes an approximate constant.

Complaints of distortion, horizontal lines having a curve, the table or street not being level, the sensation of feeling too tall or too short and stepping too high to clear the curbstone are familiar to all of us. They are due to unaccustomed degrees of correction, unfamiliar cylinders, or spherical aberration through the periphery of lenses. Explanation and time resolve these difficulties.

Anisometropia entails difficulties. An obviously impossible combination should not be prescribed. The possibility of discomfort can often be foreseen and, if the patient is forewarned, a subsequent necessary reduction in strength of the offending glass presents no embarrassing difficulties.

REFLECTIONS

Reflections cause bitter complaint from some individuals. This is especially frequent with low minus corrections, where the total spherocylindrical strength is within $0.50D$. or $0.75D$. I have tried various transpositions without benefit. Recently the Balcote film has become available for civilian use. This reduces the reflected light from approximately four

percent to less than two percent and affords some measure of relief. I have not had an opportunity to try it in those individuals who complain of four headlights on an approaching car gradually merging to two.

MUSCLES

Discomfort from disturbance of the accommodation-convergence reflex is common. An increased plus correction either for distance or near entails a relative increase in convergence and relaxation of accommodation, and conversely an increase in minus entails more accommodation with no increase in convergence. This is more frequent in the farsighted person or presbyope and is especially marked with convergence insufficiency. Time will often adjust matters and explanation helps the patient's state of mind. If convergence insufficiency is present, appropriate exercises are of great help. In an occasional case I have prescribed prisms base in for close work, but this is without remedial virtue and should be avoided if possible.

If vertical prisms have been prescribed, there may be overcorrection because the finding was temporary, possibly due to vertical maladjustment of former lenses, or because the measurement was made with maladjusted trial frames. If the Maddox rod shows overcorrection in the finished glasses the prism must be reduced or eliminated. The patient may be wearing the glasses intermittently and he may experience confusion each time they are put on or removed. The vertical muscle imbalance may not be concomitant so that the prism is incorrect for certain frequently used directions of gaze. Latent muscle imbalance may be present to be revealed by cover testing. Several times I have found the covered eye to turn up whichever it be; that is, right hyperphoria manifested by occluding the right

lens and left hyperphoria by occluding the left lens. Unless the hyperphoria remains on the same side with either eye occluded, I do not use a vertical prism.

PRESBYOPIA

Presbyopia entails its peculiar pitfalls. In the incipient presbyope it is essential to avoid bifocals until they are necessitated by the conditions of ocular use of the particular individual. An addition for near may be of comfort for prolonged close work but a bifocal for constant wear will not be satisfactory if there be not a distinct improvement in visual acuity with the lower segment. A bifocal is a crutch. He who can walk without a crutch will not use one. There must be sufficiently distinct improvement for the aid to be appreciated. In this regard, housewives are a particular stumbling block. I make it a custom, with infrequent exceptions, not to prescribe bifocals until housewives cannot see the print in the telephone book. By that time it is a nuisance to run upstairs for the reading glasses and all is well.

The focal distance of the addition for near must suit the patient's occupation and, of course, the older he is the more important it is to place the remaining accommodative range at the most serviceable distance. Stenographers want to see their copy, see the typing and still read at a reasonably (or unreasonably) close range. Carpenters want to see their thumb on starting a saw and the far end of the board, and still have clear vision at infinity and for reading. Music teachers want to read, play the piano, stand behind their pupils, and still have the piano score clear. Violinists want to read music on a distant stand and see the conductor. A lumber grader achieved relative comfort from trifocals. Timber cruisers have to be able to see their notations but are bothered by the lower segment when

walking a rough trail. Store clerks complain that they have to stoop to write sales slips and can't see the price tags on shelves through the upper segment. A similar difficulty exists for postal employees sorting mail. Dentists work at a very close range. Otologists must have a segment that will come behind the head mirror aperture. A refractionist must be able to see the trail frames without tilting his head back and an ophthalmic surgeon must have acute vision at his customary working distance.

This is all related to the most frequent complaint arising from bifocals; namely, blurring in the intermediate distance which increases with each successive increase in aid. Some patients are satisfied with an explanation. Many require a careful analysis of the various conditions of their ocular work. The difficulties can be met by segments of different heights, separate glasses for specialized purposes, or, less frequently, by trifocals. It takes time to analyze the person's needs and to evaluate his personality. It takes ingenuity to solve some of the more complicated demands. Starting with the premise that glasses can be made to give clear vision at any given distance and direction of gaze a solution can usually be found. Sometimes the patient does not have the adaptability or stamina to accustom himself to the prothesis.

The most common mistake is to overcorrect the presbyopia. Despite assiduous care and a constant awareness of this danger it still happens. When encountered, unless it is due to lack of tilting as previously mentioned, admit the fault, smile charmingly, commiserate with the patient, and obtain new lenses. It is more likely to happen when the acceptance for 6 meters shows increased plus and the addition for near is also stepped up. For example: A patient has been wearing +1.50D. with a +1.50D. add, making a

total of 3.00D. He now accepts +2.00D. for distance and being older you increase the add to 2.00D., making a total of +4.00D., and he finds the reading distance too close. When the plus acceptance for distance increases, the patient may be comfortable with no increase in the addition for near.

On the other hand, with lenticular intumescence the patient has frequently accustomed himself to read at 9 or 10 inches. With an increased minus lens for distance and an addition appropriate for his age allowing him to read at 14 inches, he is dissatisfied. These persons desire excessively strong lower segments, particularly if lenticular opacities are present, in order to obtain a larger image.

Inequalities in accommodation will account for some complaints and should be compensated. In a unique instance, in incipient presbyopia without discoverable organic disease, to explain a unilateral accommodative weakness I prescribed reading glasses with a unilateral addition and achieved success.

Some patients will complain of blurring across the room. They have become accustomed to clear vision at this distance by wearing an overcorrection for infinity. They are happier with an extra quarter or half diopter in the upper segment even though it blurs somewhat at the horizon.

Elderly persons with lenticular opacities sometimes expect miracles. With the old glasses they may have had only 6/15 vision and with the new, 6/9+, but they are dissatisfied that the visual acuity of youth is not restored. To explain is simple; to make them contented is difficult, especially if complicated by the hardheadedness of cerebral arteriosclerosis.

Occasional persons will not persevere with cylinders until they are unconscious of them. This is particularly true of the advanced presbyope who is wearing glasses for the first time. It is sometimes

better to remove the cylinders at the sacrifice of some visual acuity, and it is always better to do so before a smart competitor does it for you.

Rapid changes in refraction may be due to glycosuria but there is an occasional patient of advanced years who will accept radically different corrections on repeated examination. The first having proved unsatisfactory, the individual returns, and after the usual sleuthing, you repeat the examination with a markedly discrepant result. I have recently been a near candidate for commitment because a woman, aged 72 years, would vary in the left eye from a minus 0.5D. cylinder to a plus 1.00D. cylinder with the axis ranging from 180° to 45° . The prevention is repeated refraction before prescription. The solution is to give the weakest possible cylinder with which good vision is obtained. The final axis is probably an approximation but will be more accurate if testing be intermittent and not pressed to or beyond the point of fatigue, and will be progressively less important as the cylinder is reduced.

SPECIAL PROBLEMS

Aphakia presents its special problems. In monocular aphakia, comfort can be increased by occluding the less serviceable eye with a frosted glass or black paper. The absence of accommodation (with very rare exceptions), the necessity of thick lenses, and the consequent aberration combined with the age of the patient require considerable stamina and adaptability and frequently much explanation on the part of the physician. I believe many persons are happier with visual acuity of 6/12 and 6/45, with binocular vision and an ordinary correction, than with 6/6 or 6/5 and monocular vision with a thick lens. For this reason (and others) I do not rush into extraction of partially cataractous lenses. One

bilateral postoperative cataract case complained of both vertical and horizontal diplopia after the second eye was corrected. The vertical error was relieved by proper adjustment of lenses and the horizontal by convergence exercises.

A few unique situations deserve special mention. A letter from a patient wearing bifocals stated he could not see bulletin boards. Correspondence failed to clarify the difficulty. When he returned to the office, the situation was this: He was deformed with spinal arthritis so that his head was inclined forward. In order to bring his eyes to bear on the bulletin board he had to lean back against the opposite wall. This placed the bulletin board in the intermediate blurred area. The difficulty was resolved by a pair of "fit-overs" of the proper focal distance.

Another patient has a slight paresis of the left external rectus, due to which he is accustomed to hold his head slightly rotated to the left. He had never been able to wear bifocals with comfort. By decentering each lens one millimeter to the right he was relieved.

A patient, with an inferior surgical coloboma of the left eye resulting from trauma, was bothered by dazzling. He had no discomfort in the uninjured eye. A prescription incorporating a clear lens for the normal eye and a No. 4 soft light for the injured eye gave relief.

NONREFRACTIVE ASTHENOPA

Improper lighting explains some cases of persistent complaint. Fluorescent lighting is particularly at fault, less so now, but it is far from perfect. Insufficient or excessive light in relation to the work performed may be the cause. Sufficient light for reading is insufficient for drafting, or picking flaws in metal specimens, or sewing black cloth with black thread. Excessive light may be tiring. Concentrated, circumscribed illumination

may cause "spotlight fatigue." According to Ferree and Rand, an extreme contrast of 1:50 is the limit of tolerance. I believe it is lower. Glare may be direct, reflected, or due to improper relation between source and object. Complete search for the abstruse causes of asthenopia should include a survey of the patient's environment with a light meter. This is, of course, impracticable.

Systemic disease may be the answer. Ocular function requires muscular activity and any systemic fault which lowers muscular tone, from anemia to myasthenia gravis may produce asthenopia. Close work in excess of the individual's capacity may produce simple fatigue. The menarche and menopause cause a manifestation of symptoms otherwise disregarded. A child may have psychologic reading or writing problems unrelated to refraction error. There may be vitamin-A deficiency. Nasal congestion, obstruction, or sinus infection may produce symptoms indistinguishable from refractive asthenopia.

Or there may be aniseikonia. I mention this to avoid the criticism of omission. I am unable to distinguish the symptoms of this disorder from those arising from refractive error or muscle imbalance, and am geographically located so that I have no experience therewith.

GENERAL REMARKS

It is true that some persons do not have the stamina to accustom themselves to glasses. They have similar difficulty with dentures, wooden legs, crutches, and new shoes. There is a little of this trait in all males who love to hang on to an old hat. However, it is easy to label the patient neurotic or neurasthenic and this should never be done without exhaustive investigation. Even then I would rather consider him hypersensitive. I believe it has been established that some individuals ac-

tually feel more pain from a given stimulus than others. Aesthetically it is certainly true that some individuals are offended by inharmonious colors more than others. In the realm of sensory stimulation, but at the other extreme, some people live in contented symbiosis with pediculi while others are much disturbed by the stimuli of these "poor weak timorous beasties." Or consider the classical example of the man in bed New Year's morning, suffering from postimbibition syndrome and cringing from the raucous cacophony of the kitten stamping across the Persian carpet. My point is that we must consider the threshold of pain or discomfort in a given individual, seek out any discoverable cause by exhaustive search, and correct it if it be remediable, before we consign the patient (with private imprecations) to a life of travail wandering in an ever widening orbit from refractionist to refractionist.

Many causes of dissatisfaction can be obviated at the original examination. There is occasionally an obvious clash between the personality of the doctor and the patient. I know of one instance where a difficult female was taken aside by the office nurse and told, "Oh, please don't make doctor angry; it upsets him so!" Obviously, she never thought she had been properly refracted. The tempo of the refraction must be adjusted to the patient's ability to perceive difference and his reaction time. It is unwise to rush a person without training in visual distinction. It is easier to refract a surveyor or a microscopist than a chef. It is quicker to refract a Latin than a Scandinavian. Some persons apparently can't perceive a difference of a half diopter. Others can split an eighth and consistently estimate an axis to 0.5 degrees. Some patients are obtuse and indifferent and fail to register gross differences. Others are apprehensive, afraid of giving inconsistent an-

swers, and can always find a difference between a $+0.12D$. and a $+0.12D$. To avoid later complaints assure the patient of the correctness of his answers. Adjust the tempo of the procedure to the reaction time of the patient. Create no impression of hurry. When the prescription is given, foresee as many difficulties as possible due to any of the reasons touched upon in the foregoing and life will be a little smoother. And if the patient returns dissatisfied, accord him every courtesy and all the facilities at your command to restore him to health, which means, by one definition, to put him in perfect accord with his environment.

SUMMARY AND CONCLUSIONS

1. The dissatisfied refraction patient deserves our time to hear his complaints.
2. Usual and unusual causes of complaint are grouped and discussed.
3. Every effort should be made to locate the difficulty and correct it.
4. A patient explanation of irremediable difficulties should be made.
5. The obligation of the refractionist is not discharged until the patient is comfortable in his eyes and contented in his mind.

PROCEEDINGS OF THE ALL-INDIA OPHTHALMOLOGICAL SOCIETY

SESSION 1945, VOLUME 8

This report contains the transactions of the scientific sessions, minutes of meetings, and membership lists. The first part of the program was a symposium on glaucoma dealt with by six writers from the point of view of etiology, symptomatology, treatment, the Bengal epidemic of dropsy glaucoma, and gonioscopy. Epidemic dropsy glaucoma is one of the main ocular complications of epidemic dropsy. It was first recognized by Maynard in Calcutta in 1908. The incidence increased greatly until 1935. It is a primary chronic noninflammatory glaucoma.

The topics of the other 23 papers on the program are as varied as one would expect when a large number of ophthalmologists with varied interests and practices convenes. Some papers are case reports and are strikingly brief. Several deal with experience with sulfa drugs. A discussion on tuberculin therapy by S. N. Cooper is one of the longer essays. The author gives a comprehensive and thorough analysis of the essentials of our knowledge of tuberculin. He favors the therapeutic use by desensitization and states that "the eye, being an organ which exhibits the immune-allergic reaction easily, is a very sensitive balance to watch the reaction of tuberculin and for determining the dosage required for desensitization."

NOTES, CASES, INSTRUMENTS

BILATERAL OPHTHALMOPLEGIA IN ACUTE ANTERIOR POLIOMYELITIS*

EDWIN S. WRIGHT, M.D.
Glendale, California

The case to be reported is of unusual interest since it is a description of a rare condition; that is, bilateral complete ophthalmoplegia in acute anterior poliomyelitis.

Paralysis of the extraocular muscles in acute anterior poliomyelitis is not uncommon. Sautter¹ found that 19 of 669 cases of this disease exhibited symptoms of paralysis of one or more extraocular muscles. He stated that Medin found 9 cases of paralysis of one or more extraocular muscles in 64 cases of the disease; Wickman found 22 isolated cranial nerve palsies and 34 combined cranial and spinal nerve palsies in 862 cases; Leegard reported 2 cases of facial palsy, 3 cases of extraocular muscle palsy with spinal symptoms and one of ptosis with spinal symptoms in 311 cases; E. Mueller in 100 cases found 13 palsies and 3 unilateral abducens palsies.

In the New York epidemic of 1907,² an analysis of 752 cases showed 27 facial, 18 lid palsies, and 26 cases of strabismus. Emmons² found in 70 cases of the disease 7 cases of extraocular muscle paralysis and concluded that as a safe average, 10 percent of cases of acute anterior poliomyelitis show symptoms of paralysis of the extraocular muscles.

Ophthalmoplegia in acute poliomyelitis is, however, very rare. Sautter¹ recorded one case of bilateral ophthalmoplegia externa with ptosis in the left eye. Posey and Swindells³ reported one case of com-

plete bilateral external ophthalmoplegia in this disease. They cited Wickman as reporting a case from the Vienna epidemic of 1909, in which there was ophthalmoplegia with preservation of convergence, and they cited Takahashi as reporting a similar case from the same epidemic, and Uthoff as having seen one case of external ophthalmoplegia in acute anterior poliomyelitis.

Emmons² did not report such a case in his series. Hall's case⁴ did not exhibit ophthalmoplegia. Ghormley⁵ does not mention it in his series of 125 cases, but he was primarily concerned with optic neuritis. Somerset,⁶ writing on the various causes and clinical manifestations of ophthalmoplegia externa, does not mention poliomyelitis although he cites a case of conjugate deviation with ptosis which he considered due to an old encephalomyelitis. Poe⁷ described a case of ophthalmoplegia totalis, but concluded it was congenital in origin.

Reference to this symptom complex in textbooks of ophthalmology or neurology is scanty and not very illuminating. Acute anterior poliomyelitis is mentioned as a possible cause of ocular-muscle palsies by Peter.⁸ Berens⁹ mentions Wernicke's superior polioencephalitis as a cause of ophthalmoplegia, but Emmons² believes this is not an entity but is in reality infantile paralysis. Rea¹⁰ states that acute nuclear paralysis is due to an acute inflammatory process in the nuclei resembling that which produces poliomyelitis, or to hemorrhagic lesions. In his description of the ocular effects of acute poliomyelitis, ophthalmoplegia is not mentioned. Wechsler¹² does not mention ophthalmoplegia in poliomyelitis.

The pathology of acute poliomyelitis is better known. Charcot¹⁶ was apparently

* From The Department of Ophthalmology, Northwestern University Medical School, Chicago, Illinois.

the first to appreciate the significance of the anterior horn-cell degenerations, and his hypothesis of the organic lesion of poliomyelitis has, since 1941, challenged the ingenuity of all students of the pathology and pathogenesis of this disease. Roth¹⁶ thought the essential lesion was primarily an interstitial myelitis originating in the glia and the vessels. Rissler's work¹⁶ showed both changes simultaneous and dependent.

How does it happen that many apparently severe paralyses in the acute stages later recover good function? Flexner and Amoss¹⁶ answered this when they stated: "There are good grounds for believing that a considerable part of the paralyses, especially those that are not permanent, are the effect of temporary vascular impediments. The impediments are all outside the lumina of the vessels which are merely reduced in caliber through pressure; thrombi do not occur. Some of the functional disturbances are possibly, thus, anemic in origin; others are probably caused by slight degenerations and still others are undoubtedly caused by focal hemorrhages and edema. All these effects may, possibly, be recovered from; part by isolation of the cellular vascular infiltrate and re-establishment of the lumen, part by absorption of the edema and hemorrhage, and part by restoration of the mildly degenerated nerve cells. The severer degenerative and other lesions, through which actual necrosis is produced, do not become restored."

Hassin¹³ gives three features of the disease; namely, exudation, alteration, proliferation. The exudation is represented by perivascular infiltrations, the alteration by ganglion-cell degeneration, the proliferation by progressive glial phenomena and nodule formation. The morbid changes may extend throughout the entire central nervous system and become a disseminated condition.

In the early stages, the anterior horns are swollen, areolar, and vacuolated; in severe cases, there may be foci of necrosis and hemorrhages. The ganglion cells show

Fig. 1 (Wright). (A) Eyes front showing a slight divergence. No motion was observed on attempting vertical movements. (B) Attempting to look to the left. The right medial rectus was the only muscle functioning, and its action was paretic.

chromatolysis, tumefaction, and invasion by phagocytic elements. In other cases, they are merely surrounded by satellites but not invaded. The ganglion cell may disappear within 24 hours. Glial cells increase enormously in number; both oligodendroglia and microglia. Parallel with the ganglion-cell destruction and glial changes are demyelination of white fibers of the anterior horns. In advanced cases both axone and myelin are replaced by glia. This also occurs in the anterior roots. The entire lower motor neuron succumbs in a short time.

Independent of these parenchymatous changes are changes (mesodermal) in the meninges and blood vessels. There is hyperemia and round-cell infiltration, mainly of lymphocytes, and, later, plasma cells and polyblasts. These cell bodies are con-

lined to the Virchow-Robin spaces but in severe cases may invade parenchyma.

Although as a rule the changes are confined to the cord, in epidemics or severe forms the clinical picture may assume the ascending or descending type of Landry's paralysis with marked involvement of the medulla, pons, mesencephalon, basal ganglia, and even cortex. The condition may be so marked in the cortex as to be histologically indistinguishable from epidemic encephalitis. Mesodermal and parenchymatous changes may not be parallel in degree but are independent phenomena due to the same cause. Localization of lesions in poliomyelitis and epidemic encephalitis may be similar; that is, substantia nigra.

Wernicke's description of hemorrhagic superior encephalitis as given by Hassin¹³ shows hyperemia and neovascularization, degeneration of ganglion cells, and reactive glial proliferation mainly around the third ventricle. In some cases, the degenerative changes are found in the nuclei of the medulla and cranial nerves.

CASE REPORT

The following case report is that of a patient ill of acute anterior poliomyelitis during the epidemic that occurred in the Chicago area in the summer of 1946.

Miss M. R., aged 24 years, white, student nurse, entered the hospital on September 18, 1946, complaining of dizziness, diplopia, vicelike headache, and nausea. Slight nausea and dizziness had been present for five days prior to admission, but diplopia occurred on the day of admission. The preceding summer she had had intermittent headaches and nasal stuffiness, and a diagnosis of hay fever and upper respiratory infection had been made. Three weeks prior to admission she had had a severe upper respiratory tract infection, but went on a visit to Canada. On returning she began to notice the symptoms given above.

Examination showed, on admission to the hospital, enlarged cervical glands, neck somewhat stiff, with pain elicited on its movement; tonsils large and inflamed. The pharynx was inflamed and showed hypertrophied lymph follicles. Lungs showed moderate increase in breath sounds bilaterally and resonant percussion. Abdomen showed a right, lower-quadrant scar and no tenderness nor rigidity. Reflexes were: Abdominals present, biceps and triceps equal but diminished, knee and ankle jerks active and equal. Temperature was 103° F.; pulse, 120; respirations, 24.

Ophthalmic examination revealed no nystagmus. Both eyes were deviated outward, although the left eye deviated less. Each eye retained a weak power of external rotation and could make feeble vertical movements when abducted. Convergence was absent, but there was still some activity of the medial recti since on covering alternate eyes the uncovered eye swung back from abduction to fix near the midline. Both pupils were small but responded feebly to light. The patient could not read 12-point type at any distance.

Spinal fluid findings were: Total protein 86.8 mg.; W.B.C. 58 (60 percent lymphocytes; 40 percent polymorphonuclear leukocytes). Five days later the spinal fluid findings were the same plus a negative Kahn and a gold curve of 1-1-2-2-2-1-000.

Nose and throat cultures showed *Staphylococcus albus* and *aureus*, diphtheroids, pneumococci, and *M. tetragenous*.

The blood count was: R.B.C., 4,730,000; W.B.C., 10,350 (with 71 percent filament neutrophils, 7 percent eosinophils, 1 percent basophils, and 21 percent lymphocytes). The urine was normal.

Six days later, bilateral ptosis was noted as well as weakness of the muscles of the
